Anticholinergic agents reduce bladder tone and may lead to urinary retention. This is especially a problem for an elderly man with prostatic hypertrophy and increases the risk of urinary tract infections. In many patients with anticholinergic toxicity, urinary retention may necessitate the use of bladder catheterization. If not addressed early, significant urinary retention may further contribute to agitation.

Diagnosis

Laboratory Tests

In the United States, many toxicologic screens are immunoassays designed to detect common drugs of abuse at levels above the US Substance Abuse and Mental Health Services Administration thresholds. This type of drug of abuse screen does not detect any of the anticholinergic agents listed in Table 1. Some immunoassay screens also provide qualitative or semiquantitative detection

of TCAs or other analytes, such as methylenedioxymethamphetamine (“ecstasy”). Gas chromatography combined with mass spectroscopy is a commonly employed technique in comprehensive drug and substance screening that can detect many but not all of these agents [63, 64]. Although quantitative assays are available for most anticholinergic agents, they are usually unnecessary in the clinical management of patients with anticholinergic syndrome and rarely can be done in a clinically useful time frame. In certain cases (e.g., in fatalities or atypical presentations), other laboratory techniques (e.g., gas–liquid chromatography, high-pressure liquid chromatography, or high-pressure thin-layer chromatography) may be required to identify the anticholinergic agent.

Differential Diagnosis

The differential diagnosis includes many conditions that resemble the anticholinergic syndrome (Table 6). Many of these diagnoses can be eliminated by a careful history and physical examination combined with routine laboratory tests. A history of anticholinergic exposure, typical manifestations of peripheral and central anticholinergic toxicity, and a typical time course for resolution of clinical effects are adequate for most clinical diagnoses of anticholinergic syndrome. In some cases, little to no peripheral anticholinergic findings are noted [4]. Although several physical findings, such as dry skin and decreased bowel sounds, are said to be useful in distinguishing anticholinergic syndrome from other causes of agitated delirium, the sensitivity and specificity of these findings are not well documented. Hall and colleagues [4] stated that hyperthermia was seen in only 20% of adults and 25% of children and that fewer than 10% of patients with central anticholinergic toxicity manifest constipation, ileus, urinary retention, and convulsions. These percentages appear to be estimates, and the number of cases on which they were based was not provided. This report also stated that the most reliable signs of the anticholinergic syndrome

Table 6 Differential diagnoses of anticholinergic syndromes

Intoxications
Caffeine
Dextromethorphan
Ketamine
Lithium
Lysergic acid diethylamide (LSD)
Monoamine oxidase inhibitors (MAOI)
Phencyclidine (PCP)
Salicylates
Selective serotonin reuptake inhibitors
Sympathomimetics (e.g., cocaine, amphetamines, methamphetamines)
Theophylline
Withdrawal syndromes
Ethanol
Barbiturates
Sedative-hypnotics
Dysautonomia
Malignant hyperthermia
Neuroleptic malignant syndrome
Serotonin syndrome
Metabolic diseases
Disulfiram (Antabuse) reactions
Hepatic failure
Hypercapnia
Hyperthyroidism
Hypoglycemia
Hyponatremia
Hypoxia
Pheochromocytoma
Uremia
Wernicke’s syndrome

Other causes
Cerebral vasculitis
Cerebrovascular accident
Cerebral contusion
Postictal state
Postconcussive syndrome
Partial complex seizures
Anti-NMDA-receptor encephalitis

were dilated and sluggishly reactive pupils, confusion, disorientation, incoherence, memory impairment, facial flushing, dry mucous membranes, tachycardia, agitation, picking or grasping movements, ataxia, motor incoordination, and visual and auditory hallucinations [4]. In eight victims of surreptitious scopolamine use, dry mouth and skin were noted in 100% and decreased bowel sounds were noted in 25% [42]. Published reviews of *Datura stramonium* (Jimson weed) intoxication signs report wide ranges of clinical antimuscarinic features with dry mucous membranes and dry skin present in 46–94% of patients [65, 66]. In unknown cases, comprehensive laboratory testing can be used to detect some of the more commonly used drugs and abused substances.

Diagnostic Studies

Toxicologic Analyses

Most of the common causes of the anticholinergic syndrome are not detected on routine toxicologic screens, which usually consist of immunoassays to detect drugs of abuse. An exception is the qualitative immunoassay for TCAs, which also can yield false-positive results in the presence of other anticholinergic drugs, such as diphenhydramine and certain phenothiazines and anticonvulsants such as carbamazepine. Although quantitative levels of most of the drugs and anticholinergic alkaloids in Table 1 are available from reference laboratories, they are rarely necessary. Because of variable susceptibility to these agents, quantitative levels for diagnostic confirmation may not be reliable [67]. Quantitative levels of other agents may be useful in ruling out the anticholinergic syndrome.

Abnormal Routine Laboratory Test Findings

Many standard laboratory tests may be abnormal in patients with the anticholinergic syndrome. Patients who are agitated or delirious may have a mild increase in white blood cell counts secondary to demargination. Increases in serum sodium,

urine osmolality, blood urea nitrogen, and creatinine may occur as a result of prerenal azotemia secondary to poor fluid intake and increased insensible losses associated with agitation and hyperthermia. Increased creatinine also may occur with rhabdomyolysis-induced acute renal failure. Hyperthermia and agitation may lead to rhabdomyolysis, which is associated with increased amounts of myoglobin in the serum and the urine. Urine with excess myoglobin appears brown or pink and tests positive on a urine orthotolidine test for blood, but no red blood cells are seen in the microscopic urinalysis. Quantitative serum concentrations of skeletal muscle enzymes, particularly creatinine phosphokinase, and urinary myoglobin levels can confirm the diagnosis of rhabdomyolysis. Rhabdomyolysis also may increase the serum potassium and phosphate concentrations and decrease the serum calcium levels. Marked agitation may be associated with an increased anion gap metabolic acidosis, increased serum lactate, and decreased serum bicarbonate. Sustained or severe hyperthermia may result in disseminated intravascular coagulation, characterized by increased coagulation times, increased D-dimer and fibrin split products, and decreased platelets and fibrinogen levels.

Differential Features

The anticholinergic syndrome may be characterized by the mnemonic “*mad as a hatter, red as a beet, dry as a bone, blind as a bat, hot as a hare and tachy as a leisure suit.*” The syndrome is usually, but not always, a combination of peripheral and central anticholinergic toxicity (see Table 4). When it occurs without signs of peripheral anticholinergic toxicity, the anticholinergic syndrome may be misdiagnosed as a primary psychiatric disease, especially without a history of excess anticholinergic exposure and with a negative toxicologic screen [68]. Misdiagnoses are more common in very young and very old patients [23, 69, 70]. Anti- *N*-methyl-D-aspartic acid receptor encephalitis is an important recently described syndrome occurring primarily in young females that may closely mimic features of both central and peripheral anticholinergic

toxicity as a result of paraneoplastic effects (most commonly ovarian teratoma) [71, 72]. Many other toxicities and medical problems may also resemble the anticholinergic syndrome and may be difficult to distinguish clinically (see Table 6). Although it is said that dry skin and absent bowel sounds distinguish anticholinergic syndrome from stimulant poisoning, there are few published data to evaluate the sensitivity or specificity of these findings. Ophthalmologic preparations are particularly problematic because many patients do not include them when listing their current medications [28]. In a suspected case of anticholinergic syndrome, a diagnostic challenge with physostigmine doses may be attempted as long as contraindications (see ► Chap. 161, “Physostigmine”) are not present [73].

Treatment

Most cases of the anticholinergic syndrome are not life-threatening and require little more than observation and general supportive care. Because these patients are at risk of hurting themselves or others and of sudden deterioration due to seizures or respiratory distress, they should be observed carefully until major signs of toxicity have dissipated. Less commonly encountered severe cases may require complicated and expert supportive care [74, 75]. More severe cases of the anticholinergic syndrome usually are seen with agents that have other important, potentially toxic properties, such as sodium channel or α -adrenergic receptor blockade (e.g., TCAs, neuroleptics, diphenhydramine). Delayed gastric emptying and drug absorption are major concerns. In a reported case of severe benztropine toxicity, severe anticholinergic poisoning persisted for 9 days after a large single ingestion [76]. Anecdotally, one author reported recovery of Jimson weed seeds 23 h after ingestion [77]. A review of 15 cases of anticholinergic plant poisoning reported a mean latency to onset of symptoms of 2.7 h [78]. Based on these reports, gastrointestinal decontamination with activated charcoal may be useful for a longer time after ingestion of these agents than for the usual types of acute overdose

(Grade III recommendation). However, activated charcoal has not been shown to affect the outcome of these patients. The administration of activated charcoal should be done cautiously, if at all, in patients with altered mentation or risk of seizures, unless their airways are mechanically protected. Patients with severe toxicity and patients who are unable to protect their airway should undergo rapid-sequence intubation.

Patients who are significantly agitated must be protected from hurting themselves or others. Significant agitation associated with the anticholinergic syndrome should be treated by reversal with either an anticholinesterase (i.e., physostigmine) or a sedating agent (chemical restraint) (Grade I recommendation). The use of physical restraints alone may result in significant rhabdomyolysis if the patient fights vigorously or persistently against them. Physical restraint should be used only as an adjunct to chemical restraints, in case the latter wear off unexpectedly. Large amounts of sedatives may be required to achieve adequate chemical restraint or sedation in anticholinergic syndrome cases. In a comparative study of physostigmine versus benzodiazepines for the anticholinergic syndrome, the mean total benzodiazepine doses were diazepam, 53.1 mg; lorazepam, 35.5 mg; and midazolam, 31.7 mg [79]. Watkins et al. demonstrated the use of physostigmine alone resulted in significantly lower rates of intubation compared to benzodiazepines alone or a combination with other sedating agents [80]. Haloperidol can be used to calm delirious patients, but concerns about QT_c interval prolongation and proarrhythmias warrant QT_c monitoring during its use [81, 82]. Because haloperidol has some mild anticholinergic properties, many medical toxicologists believe it should be avoided in patients with the anticholinergic syndrome. However, published systematic reviews have not demonstrated any significance difference in outcomes or adverse effects between typical and atypical antipsychotics in the setting of all-cause delirium [83, 84]. As there exist no published clinical studies with respect to typical or atypical antipsychotic use in the specific setting of acute anticholinergic-induced delirium, the above concerns remain theoretical.

Seizures may be seen in severe cases of anticholinergic toxicity. Although apparent successful terminations of anticholinergic-associated seizures with physostigmine have been reported [85, 86], seizures believed to be secondary to physostigmine use also have been reported [87–89]. Animal studies suggest that physostigmine has limited efficacy against seizures secondary to anticholinergic toxicity [90–93]. Because of concerns over limited efficacy and even enhancing propensity to seizures, physostigmine is not indicated as an anticonvulsant therapy. Benzodiazepines are the primary anticonvulsants for anticholinergic-induced seizures. Seizures refractory to benzodiazepines may be treated with barbiturates or propofol as a second line agents (Grade III recommendation). Patients not responsive to those agents may be treated as described in ► Chap. 20, “Toxicant-Induced Seizures.”

Severe hyperthermia (temperature $>40^{\circ}\text{C}$) may result in direct tissue injury and rapid cardiovascular collapse and therefore should be treated aggressively. In addition to liberal doses of benzodiazepines to decrease adrenergic tone, rapid cooling is mandatory (Grade II-2 recommendation). Ice water immersion provides the most rapid reduction in core body temperature, albeit potentially limited by logistical constraints [94]. Other methods of cooling include ice-cooled saline infusion, evaporative methods (wet sheets and fans), and ice packs to the axilla and groin. Novel cooling devices developed for post-cardiac arrest target temperature management have received limited study but appear to be inadequate [94]. Dantrolene sodium occasionally appears as a recommended adjunctive agent for toxicant-induced hyperthermia. While there appears to be some evidence in its use for neuroleptic malignant syndrome, there is no published data supporting its use in anticholinergic-induced hyperthermia [95–99]. Instead, severe muscular rigidity that does not respond to benzodiazepines should be met with neuromuscular paralysis to eliminate continued thermogenesis [94].

Rhabdomyolysis may occur secondary to marked agitation, increased muscle tone, or severe hyperthermia. In the absence of renal failure, rhabdomyolysis treatment includes early liberal

administration of intravenous fluids (Grade I recommendation), though the benefit of adding mannitol or sodium bicarbonate is less clear. Myoglobin is less likely to precipitate in the renal tubules and cause nephrotoxicity when the urine is dilute and alkaline [100, 101].

Specific Treatment

Some physicians prefer to treat the anticholinergic syndrome primarily with supportive care, carefully titrated sedation, and intubation and artificial ventilation if necessary [102]. Other physicians prefer to use physostigmine for cases of severe anticholinergic poisoning presenting without significant cardiovascular toxicity, in hopes of avoiding the need for excess sedation, intubation, and artificial ventilation [70]. This is further supported by Watkins et al. who found that, in patients with severe anticholinergic-induced agitation, the use of physostigmine alone resulted in significantly lower rates of intubation compared to benzodiazepines (1.8 vs. 8.4%, respectively) [80]. Physostigmine is a short-acting, nonselective cholinesterase inhibitor that is a tertiary amine capable of crossing the blood–brain barrier. It has been reported to be effective in reversing anticholinergic toxicity from drugs [79, 103–105] and natural substances. (The clinical pharmacology of this agent is discussed in detail in ► Chap. 161, “Physostigmine.”) [106, 107] Although physostigmine was popular in the 1970s and early 1980s, its use diminished after reports of serious adverse effects in TCA overdoses [108–110]. Currently the use of physostigmine to reverse central anticholinergic toxicity remains somewhat controversial among some emergency medicine physicians.¹¹² Many of these perceived risks seem to be unfounded in the eyes of the medical toxicology community.¹¹² Doses of 2 mg (or 0.02 mg/kg) of physostigmine over 2 min will reliably reverse anticholinergic syndromes. The pharmacokinetic half-life of physostigmine is approximately 20 min, although the pharmacodynamic effect lasts longer. Nevertheless, it is not uncommon for the clinical effect of physostigmine to wear off before the

anticholinergic delirium resolves. In these cases, physostigmine can be readministered. Because of its cholinergic properties, physostigmine is best avoided in patients with significant bradycardia or active bronchospasm. Further details regarding the use of this agent are provided in ► **Chap. 161, “Physostigmine.”** Neostigmine is a quaternary amine, unable to cross the blood–brain barrier. It has been reported to be more efficacious than physostigmine in the treatment of paralytic ileus and other peripheral anticholinergic effects, but supportive care, supplemented by physostigmine as necessary, is preferable [96].

Key Points

- Serotonin syndrome can occur with the initiation, dose escalation, or an overdose of serotonergic agents.
- The diagnosis of the serotonin syndrome is based on an accurate history of exposure to a serotonergic agent and bedside clinical exam.
- Rapid control of muscle rigidity and clonus is accomplished through administration of benzodiazepines.
- Hyperpyrexia is a marker of worsening serotonin syndrome and should be aggressively corrected by musculoskeletal paralysis and orotracheal intubation.

Common Errors

- Failure to recognize development of mild serotonin syndrome after change in dosage of serotonergic agents
- Failure to recognize the rapid progression of serotonin syndrome
- Misdiagnosis of anticholinergic toxidrome, neuroleptic malignant syndrome, or malignant hyperthermia

Criteria for ICU Admission

- Significant clonus, tachycardia, and altered mental status unresponsive to benzodiazepines
- Muscle group rigidity and hyperthermia (temperature $>41^{\circ}\text{C}$) requiring active cooling

Criteria for ICU Discharge

- Resolution of clonus and altered mental status
- Resolution of hyperthermia and decreasing benzodiazepine requirement

The serotonin syndrome (SS) is a triad of altered mental status, autonomic instability, and neuromuscular abnormalities that presents following overdose, inadvertent dose escalation, or drug-drug interaction. While many cases can be self-limited and benign, severe cases of serotonin syndrome can be confused with neuroleptic malignant syndrome and severe metabolic and infectious etiologies.

Rarely referred to as serotonin toxicity, SS was first described in 1982 by Insel et al. who reported two patients who developed confusion, myoclonus, and fever after being treated with clomipramine, a tricyclic antidepressant [1]. Because of under-recognition and misdiagnosis, the true incidence of SS is hard to estimate [2]. The most recent toxicovigilance report from the American Association of Poison Control Centers (AAPCC) in 2014 demonstrates that poisoning from antidepressant agents (most commonly serotonin reuptake inhibitors) was the third most common reported exposure [3]. In addition, both antipsychotics and antidepressant medications that tend to have serotonergic activity were among the top ten of substances with greatest rate of increase in exposures. Selective serotonin reuptake inhibitors (SSRIs) accounted for 99 fatalities in the United States in 2014, the eighth-most common agent implicated in fatalities reported to AAPCC.

Biochemistry and Clinical Pharmacology

Serotonin syndrome is the result of excessive serotonin (5-hydroxytryptamine, 5-HT) at the synapse. Only about 5% of the body's 5-HT is located in the central nervous system, with most of the remainder being stored in enterochromaffin cells in the small intestine and circulating platelets. Serotonin is synthesized in the brain and in enterochromaffin cells from the amino acid L-tryptophan (Fig. 1)). L-tryptophan is transported across the blood-brain barrier through a nonspecific amino acid transporter and is hydroxylated to form 5-hydroxytryptophan which is then decarboxylated to 5-hydroxytryptamine. Serotonin is secured in intracellular vesicles through transport from the vesicular monoamine transporter (VMAT2). During neuronal depolarization, vesicles fuse with the presynaptic cleft and release 5-HT which binds to specific serotonin receptors at the postsynaptic junction. To date, there are seven known families of serotonin receptors (5-HT₁, 5-HT₂, 5-HT₃, 5-HT₄, 5-HT₅, 5-HT₆, and 5-HT₇) [4–6]. Some of these families contain separate subtypes of receptors. Six of these families are composed of G-coupled receptors with protein channels that respond to binding of 5-HT by altering neuronal membrane potential [5]. In contrast, the 5HT₃ receptor is a ligand-gated ion channel. 5-HT₁ receptors located within somatodendritic cells in the central nervous system (CNS) regulate mood. The 5-HT_{1B} receptor subtype is found peripherally on smooth muscle cells in vasculature. Agonism of 5-HT_{1B} receptors by triptans produces vasoconstriction, thus mitigating headaches. 5-HT₂ receptors are also found centrally and work in conjunction with 5-HT₁ receptors to regulate mood, nociception, and muscle tone [7]. 5-HT_{2A} and 5-HT_{2B} receptors are found in the gut and cardiac myocytes and may function to mediate long-term cardiac remodeling [8–10]. Agonism of 5-HT₂ receptors may also be responsible for cardiac valvulopathies associated with the use of some medications [11]. 5-HT₃ receptors in the gastric fundus, ileum, and the brainstem's dorsal vagal complex modulate

Fig. 1 Serotonin receptors and drug targets

nausea [4]. Of the families of serotonin receptors, activation of 5-HT_{1A} and 5-HT_{2A} receptors is largely responsible for the autonomic and neurologic manifestations seen in SS [8, 12, 13]. In overdose, however, the loss of receptor selectivity from binding at multiple 5-HT receptors contributes to the development of SS [14] (Fig. 2).

Regulation of serotonin concentrations in the synapse is accomplished by two methods: (1) release of serotonin from the afferent neuron into the synaptic junction inhibits further vesicular

fusion and release of 5-HT, and (2) degradation by monoamine oxidase A (MAO-A), an intraneuronal enzyme with affinity for 5-HT and norepinephrine [15]. Disruption in this cycle (e.g., excessive release of neurotransmitter, decreased reuptake of serotonin into the afferent neuron, and inhibition of metabolism) causes persistent stimulation of serotonin receptors and the clinical effects observed in SS.

Most serotonergic xenobiotics modulate serotonin expression within the CNS in a variety of ways (Table 1) [16]. While overdose of a single serotonergic agent may be sufficient to induce SS, most cases arise from combinations of xenobiotics that affect serotonin in a different ways [17]. For example, cocaine can cause an increase in release of 5-HT (also dopamine and norepinephrine) by inducing vesicle fusion with the presynaptic junction. It also prevents reuptake of HT, a combination of actions that can induce SS [18, 19]. Combinations of drugs that both prevent reuptake and decrease metabolism of 5-HT can also produce SS. For example, patients on therapeutic dosing of SSRIs who receive the MAO-A inhibiting antibiotic linezolid, or are placed on other MAO-A inhibitors, can experience serotonin syndrome as both reuptake and metabolism of 5-HT are inhibited [20, 21].

Clinical Presentation and Life-Threatening Complications

The presentation of patients with an SS ranges from subtle changes in mental status to obtundation, neuromuscular rigidity, and hyperthermia [22]. Approximately 60% of patients with SS will present within 6 h of initial use of a serotonergic medication, an overdose, or change in medication [23]. These patients may present lucid and, as the drug is absorbed over the course of time and become somnolent, develop hyperreflexia, clonus, and tachycardia as they progress through the spectrum of SS.

Mild SS may present as a subtle change in mental status or mild confusion accompanied by hyperreflexia or tremor in patients receiving a

Fig. 2 Clinical manifestations of serotonin syndrome

serotonergic agent. Vital sign abnormalities in mild SS may include tachycardia. Patients with moderate poisoning may exhibit clonus, hyperreflexia, and tachycardia. Interestingly, hyperreflexia and clonus in moderate cases of SS tend to be greater in the lower extremities. Altered mental status can range from sedation to mild agitation or hypervigilance, and patients may exhibit pressured speech [22]. Patients with moderate SS may exhibit hypertension and tachycardia.

Altered mental status, inextinguishable clonus, diaphoresis, rigidity, and hyperthermia are hallmarks of severe SS [17]. While hypertension and tachycardia are common, patients may have striking changes in pulse and blood pressure accompanied by hyperthermia. Excessive neuromuscular activity leads to rigidity, which, in turn, culminates in hyperthermia. End-organ injury results from hyperthermia and can be detected as rhabdomyolysis, acute kidney injury, elevations in aminotransferases, and signs of disseminated intravascular coagulation [24]. The

presence of seizures in severe serotonin syndrome is uncommon but may arise in severely hyperthermic patients.

Diagnosis

No laboratory tests confirm the diagnosis of serotonin syndrome. Instead, physical examination findings (clonus, hyperreflexia, tremor, or akathisia without extrapyramidal signs) should compel the clinician to consider the diagnosis of serotonin syndrome. Several criteria have been proposed for the diagnosis of serotonin syndrome and can be applied in conjunction with a bedside clinical exam to confirm the diagnosis of SS (Table 2) [16, 22, 25]. Common among these criteria is a history of recent addition or dose escalation of a known serotonergic agent accompanied by clonus, tremor, hyperreflexia, or altered mental status.

Sternbach's original diagnostic criteria for SS were derived in 1991 from 38 reported human

Table 1 Xenobiotics that can contribute to serotonin syndrome

Increased serotonin synthesis

cases in the medical literature [25]. The Sternbach criteria for SS include historical evidence of addition or increase in a known serotonergic agent, the absence of an alternative explanation, the lack of recent administration of a neuroleptic agent, and the presence of three of the ten most common clinical features in patients with SS in his review [25]. The most common findings in patients with SS were altered mental status (42%), restlessness (45%), and myoclonus (34%) [25]. The Sternbach criteria, although 75% sensitive and 96% specific, missed early, mild, or incomplete presentations of the disorder; possibly these early criteria were

Table 2 Decision criteria for serotonin syndrome

Sternbach's criteria ^a	Hunter criteria ^b
1. Recent addition or increase of a known serotonergic agent	In the presence of a serotonergic agent:
2. Absence of other possible etiologies	1. IF (spontaneous clonus = yes) THEN serotonin toxicity = YES
3. No recent addition or increase of a neuroleptic agent	2. ELSE IF (inducible clonus = yes) AND (agitation = yes) OR (diaphoresis = yes) THEN serotonin toxicity = YES
4. Three of the following symptoms:	3. ELSE IF (ocular clonus = yes) AND (agitation = yes) OR (diaphoresis = yes) THEN serotonin toxicity = YES
Altered mental status	4. ELSE IF (tremor = yes) AND (hyperreflexia = yes) THEN serotonin toxicity = YES
Agitation	5. ELSE IF (hypertonic = yes) AND (temperature > 38 °C) AND (ocular clonus = yes) OR (inducible clonus = yes) THEN serotonin toxicity = YES
Myoclonus

heavily weighted toward the presence of altered mental status [16, 26, 27].

The Hunter serotonin toxicity criteria was derived in 2003 from a case series of 2222 patient included in a medical toxicology registry [16]. Clinical features of patients diagnosed with SS by a medical toxicologist were recorded and a decision rule was derived and validated. Similar to initial studies, confusion, hyperreflexia, and myoclonus were the most common findings associated with SS. In addition, autonomic instability in the form of tachycardia, hyperthermia, mydriasis, and diaphoresis were identified as part of the spectrum of SS. Patients with progressive SS (defined as requiring endotracheal intubation for clinically worsening SS) exhibited high fever, truncal rigidity, and peripheral hypertonicity [16, 28]. When compared with the original Sternbach's criteria, the Hunter serotonin toxicity criteria are simpler, more sensitive (84% vs. 75%), and more specific (97% vs. 96%) in the diagnosis of SS [17].

Table 3 Differential toxidrome diagnosis for serotonin syndrome

	Serotonin syndrome	Anticholinergic toxidrome	Neuroleptic malignant syndrome
Agent	SSRI, SnRI, MAO-I	Antihistamines, anticholinergics	Antipsychotics, dopaminergic drugs
Pathophysiology	Blockade of 5-HT reuptake, increased synthesis, decreased metabolism	Inhibition of cholinergic transmission at muscarinic receptors	Modulation in dopamine receptor blockade
Physical exam	Mydriasis, altered mental status, hyperreflexia, clonus, diaphoresis	Mydriasis, altered mental status, hyperreflexia, flushed skin, ileus, urinary retention	Hyperthermia, altered mental status, hypertension, muscle rigidity
Typical lab findings	Elevated CPK	Unremarkable	Elevated CPK, leukocytosis
EKG	Sinus tachycardia, prolonged QTc	Sinus tachycardia, prolonged QRS	Sinus tachycardia
Antidote	Cyproheptadine	Physostigmine	Dantrolene

Laboratory Testing

The degree of laboratory abnormalities correlates broadly with the severity of illness. Mild cases of SS frequently have no laboratory abnormalities. Depending on the degree of neuromuscular activity, creatinine phosphokinase (CPK) may be elevated. Severe elevations of CPK, aminotransferases, and serum creatinine, as well as signs of disseminated intravascular coagulation, are due to hyperthermia [22]. Additional laboratory evaluation to screen for common coingestants in the suicidal patient can help exclude other evolving toxidromes in a polypharmacy ingestion. Quantitative measurement of drug concentrations has little if any impact on patient care; the concentration of many therapeutic agents cannot be measured in a timely manner and does not correlate with clinical presentation [29]. Clinicians should note that therapeutic dosing and drug concentration, however, do not exclude the diagnosis of SS.

The most common electrocardiographic finding in patients with SS is tachycardia [30]. Because of the presence of serotonin receptors in the myocardium, alterations in membrane depolarization can occur and may result in prolongation of the QT interval. Diagnostic imaging including computed tomography (CT) and magnetic resonance imaging (MRI) of the brain in

patients who present with alterations in mental status would be expected to be unremarkable in the patient with SS.

Differential Diagnosis

The differential diagnosis for SS includes anticholinergic toxicity, sympathomimetic toxicity, neuroleptic malignant syndrome (NMS), and malignant hyperthermia (MH), all of which can be distinguished from the serotonin syndrome on clinical grounds and a careful medication history (Table 3). The presence of clonus, muscle rigidity, and medication history containing a serotonergic agent distinguish the serotonin syndrome from the anticholinergic toxidrome, neuroleptic malignant syndrome, and malignant hyperthermia. Patients with anticholinergic poisoning will have mumbling speech and will be feebly picking at objects; on physical examination, these patients have normal reflexes along with mydriasis; agitation; dry oral mucosa; hot, erythematous skin; and an absence of bowel sounds. In contrast, patients with serotonin syndrome have moist oral mucosa, erythematous and diaphoretic skin, and hyperactive bowel sounds.

Patients with a pure sympathomimetic toxidrome may exhibit similar bedside clinical findings as patients with SS, but lack clonus and

a medication history consistent with SS. Neuroleptic malignant syndrome is defined by a slow onset of bradykinesia or akinesia, “lead-pipe” muscular rigidity, hyperthermia, fluctuating consciousness and autonomic instability in contrast to the rapid onset, hyperkinesia, and clonus of serotonin syndrome [31, 32]. Although not diagnostic, a chart review of 24 patients with NMS found marked leukocytosis, while patients who initially present with tremor and myoclonus invariably were diagnosed with SS [23]. Malignant hyperthermia is a pharmacogenetic disorder characterized by hypertonicity and hyperthermia [33]. The disorder occurs within minutes after exposure to inhalational anesthetic agents. On physical exam, patients with malignant hyperthermia have mottled skin, rigor mortis-like muscle rigidity, increasing concentrations of end-tidal carbon dioxide, and hyporeflexia distinguishing the disorder from hyperreflexia, clonus, and hyperthermia found in SS [33].

Treatment

The mainstay of treatment of SS is rapid recognition of the condition, supportive care, and removal of the inciting drug [30]. With the removal of the inciting agent, provision of supportive care, control of agitation, control of autonomic instability, and control of hyperthermia, the majority of cases will resolve within 12–24 h [23, 30, 34, 35]. The intensity of management correlates with the severity of SS.

Patients with mild SS (e.g., tremor, extinguishable clonus, mild tachycardia) typically require intravenous fluid support and benzodiazepines with resolution of symptoms within 24 h [35]. Diazepam, a long-acting benzodiazepine, has been shown to provide sedation while lowering fever in animal models of SS [36].

The interventions directed toward patients who progress to moderate or severe SS should correlate with severity of disease. Whereas supportive care followed by administration of benzodiazepines may be sufficient for mild cases of SS, hypertensive and tachycardic patients may require serotonin antagonists to help control serotonergic signs. In extreme cases, hyperthermic individuals

Table 4 Treatment of serotonin syndrome

Mild serotonin syndrome	
Tachycardia, inducible clonus, hypertension	Intravenous fluids, benzodiazepines
Moderate serotonin syndrome	
Tachycardia, clonus, altered mental status, hyperthermia	Intravenous fluids, benzodiazepines, cyproheptadine, dexmedetomidine
Severe serotonin syndrome	
Tachycardia unresponsive to benzodiazepines, coma, hyperthermia, rigidity, sustained clonus, seizures	Hemodynamic support, neuromuscular paralysis, cyproheptadine, benzodiazepines, vasopressors

require paralysis with ventilator support (Table 4). Patients with autonomic instability and hypotension may require vasopressor support [14, 17, 37]. The pharmacodynamics and pharmacokinetics of the inciting agents in overdose are difficult to predict because symptoms may persist longer than occur in therapeutic dosing.

In patients with moderate SS (e.g., tachycardia, inextinguishable clonus, hyperthermia, altered mental status) who do not improve with benzodiazepines, practitioners should initiate the serotonin antagonist cyproheptadine. Typically used as an antihistamine, cyproheptadine has muscarinic and 5-HT_{2A} antagonist properties that have been shown to improve the autonomic instability associated with SS [22, 38, 39] (level of evidence (LoE) II-3). Although no human trials have demonstrated a survival benefit from cyproheptadine therapy, murine studies suggest that treatment with cyproheptadine mitigates the tremor and clonus that are refractory to benzodiazepine therapy [40]. Initial dosing starts with a 12 mg oral loading dose followed by 2 mg every 2 h until the clinical condition improves [22, 30]. If improvement is seen, a maintenance dose of 8 mg every 6 h can be administered. In children, we recommend a 0.25 mg/kg/day oral dose divided over 6 h with a maximum of 12 mg/day (LoE II-3) [22, 40, 41]. A total dose of 12–32 mg of cyproheptadine, which binds 85–95% of serotonin receptors, may be required in the first 24 h of treatment [41]. Administration of cyproheptadine in the altered

patient may be challenging as the drug is only available as an oral formulation. In cases when cyproheptadine therapy is indicated, administration via a nasogastric tube may be warranted. The correct process in which clinicians should wean cyproheptadine is unknown. We recommend tapering the cyproheptadine dose over the course of 24–48 h with careful reexamination of the patient for the recurrence of serotonergic findings. Because of its anticholinergic properties, cyproheptadine may precipitate the anticholinergic toxidrome.

Dexmedetomidine, a centrally acting α -2 agonist, has been proposed as an agent for sedation in the context of the altered patient with moderate SS who remains refractive to benzodiazepines [42] (level of evidence [LoE] II-3). The α -2 effects of dexmedetomidine may decrease secretion of serotonin through a negative feedback loop in serotonergic neurons, thus decreasing the downstream effects of altered mental status and autonomic instability [43, 44]. Dosing of dexmedetomidine starts with a bolus infusion of 0.5–1 mcg/kg over 10 min followed by a continuous infusion of 0.2–0.7 mcg/kg/h [38, 45]. Few case studies have demonstrated the ability of dexmedetomidine to control agitation and confusion potentiated by serotonergic agents without producing decreased respiratory drive or the need for orotracheal intubation [38, 42].

Patients with progressively worsening tremor, hyperthermia, tachycardia, and rhabdomyolysis require aggressive supportive therapy with high-dose benzodiazepines, intravenous fluids, and cyproheptadine. Concomitant ingestion of a MAO inhibitor can produce dramatic fluctuations in blood pressure. We recommend direct-acting sympathomimetics such as norepinephrine, phenylephrine, and epinephrine instead of indirect agents such as dopamine [22]. Before it can act as a pressor, dopamine requires metabolism into vasogenic amines whose concentration is regulated by MAO. Patients on monoamine oxidase inhibitors (MAO-I) may experience varying concentrations of vasogenic amines in response to doses of dopamine and may experience profound fluctuations in blood pressure. Severe hypertension, whether due to SS or from an unanticipated

effect of vasopressor agents, can be treated with short-acting agents such as nitroprusside or an esmolol infusion that can be titrated to desired hemodynamic effect.

Hyperthermia (core temperature greater than 41 °C) is a sign of profound neuromuscular activity from sustained tremor culminating in muscle rigidity. Hyperthermia, because it heralds significant morbidity and mortality, must be aggressively corrected by reversing its cause, excessive muscle activity, with neuromuscular paralysis, orotracheal intubation, and mechanical ventilation [14, 17, 22, 37, 46]. Antipyretics such as acetaminophen and ibuprofen are not only ineffective in controlling hyperthermia in SS but also can paradoxically worsen outcomes because of the threat of hepatic injury. We recommend a nondepolarizing paralytic agent such as rocuronium or vecuronium. Paralysis should be discontinued upon resolution of hyperthermia in addition to clinical and laboratory signs of improvement – decreasing CPK, improved hepatic and renal injury, and resolution of extremity clonus. Succinylcholine should be avoided in patients with severe serotonin syndrome as its use could precipitate hyperkalemia from rhabdomyolysis. Premature termination of paralysis can be associated with return of hyperthermia and worsening rhabdomyolysis.

Prevention of SS can be accomplished by physician education, modification in prescribing patterns, and the use of pharmacologic programs that identify drug-drug interactions [2]. Application of pharmacogenomic principles may help predict patients at risk of developing SS when exposed to serotonergic agents [47, 48]. Once toxicity occurs, consultation with a medical toxicologist, a clinical pharmacology service, or a poison control center can identify proserotonergic agents, guide treatment, assist clinicians in anticipating adverse effects, and provide valuable clinical decision-making experience. We recommend inciting serotonergic agents be discontinued for at least 48 h after resolution of the serotonin syndrome; reinitiating these medications should be done in consultation with a medical toxicologist or psychiatrist to prevent future episodes of serotonin syndrome (LoE III).

Sympathomimetics have been available as medicinal agents since antiquity. More than 5000 years ago, the ancient Chinese recognized ephedrine, the primary active ingredient from the ephedra plant *ma huang*, as an active ingredient to treat asthmatic conditions and to stanch bleeding. Pliny, in the first century AD, also used ephedrine to treat bleeding [1]. Caffeine made from brewing the seeds of the cocoa plant was used in South America and introduced to Europe in the Middle Ages. Amphetamine was introduced as a nasal decongestant, general stimulant, and anorexiant in the 1930s and its medical use continued through WWII. In the USA, the Controlled Substance Act of 1970 made amphetamine “Schedule II” substances, meaning they are deemed to have high abuse potential. Similar controls have been put in place in other countries. During the 1960s, home chemists experimented with merging various combinations of mescaline and amphetamine derivatives to yield the “alphabet soup” of hallucinogenic amphetamines. Now, in the twenty-first century, sympathomimetics are ubiquitous in daily life (Table 1). They are found in over-the-counter medications including cough and cold preparations, alternative medicinal agents, and illicit drugs. Caffeine can be found in beverages, in weight loss supplements, in coffee shops, in flavored waters; advertised to teenagers; and combined with alcoholic beverages (Table 2). Popular illicit sympathomimetics continue to include cocaine, methamphetamine, and 3,4-methylenedioxymethamphetamine (MDMA); and the most

recent wave of diversionary sympathomimetic agents include synthetic cathinones and other phenylethylamines including “2C” drugs, piperazines, and tryptamines [3].

Sympathomimetic Toxidrome

The sympathomimetic toxidrome comprises a broad constellation of signs and symptoms which reflect activation of components of the autonomic sympathetic nervous system. Although sympathomimetics are thought of as being interchangeable, there can be significant differences in

physiologic effects. These effects depend upon whether the agent has predominant effects on dopaminergic, serotonergic, or adrenergic neurotransmission; whether the agent is a direct-acting or indirect-acting agent; and which receptor subtypes are involved. The effects of specific sympathomimetic agents are described in ► [Chap. 41, “Sympathomimetic Agents.”](#) In general, the classic picture of a sympathomimetic toxidrome is a patient who presents with signs of significant adrenergic excess. This can include dilated pupils, tachycardia, tachypnea, hypertension, hyperthermia, and psychomotor agitation – the classic “fight-or-flight response.” The patient may be agitated, confused, or seizing. If the patient has been on a prolonged “speed run,” he or she may show signs of “catecholamine depletion” with lethargy, unresponsiveness, and relatively normal vital signs. This is sometimes referred to as the “crash” or “washout” syndrome. Because few illicit sympathomimetic agents are pure agonists

at a single receptor, there may be signs of other neurotransmitter effects, such as dopamine and serotonin. These effects include tremor, myoclonus, lower extremity rigidity, hypotension, hallucinations, and psychosis. Dopamine and serotonin also may contribute to the confusion, mental status changes, and seizures that cannot be explained by adrenergic stimulation alone.

Pathophysiology

Sympathomimetics are defined as catecholamine-like substances that have physiologic actions similar to those engendered by activation of the autonomic sympathetic nervous system. These actions include an excitatory effect on some types of smooth muscle with an inhibitory effect on others, modulation of glycogenolysis in the liver and muscle, and alterations in free fatty acid metabolism in adipose tissues with muscle thermogenesis via β_3 receptors. In some cases, sympathomimetics alter the effects of insulin by affecting the islet α_2 receptors and β_2 receptors and pituitary hormone secretion (antidiuretic hormone) by stimulation of central β_1 receptors [4]. The most clinically salient effects are those that involve the heart and central nervous system (CNS). Sympathomimetics have an excitatory effect on the heart, enhancing both inotropy and chronotropy. Agents that cross the blood–brain barrier stimulate the CNS to increase wakefulness and psychomotor activity. Most have an anorexiant effect.

Structurally, many sympathomimetics are derived from a β -phenylethylamine (phenethylamine) parent compound (Fig. 1). Sympathomimetics with adjacent dihydroxy ($-\text{OH}$) substitutions on the benzene ring are called *catecholamines*. By altering the location of the hydroxyl groups on the phenyl ring and the size and location of the alkyl substitutions on the ethylamine moiety, the molecule can assume variable α and β selectivity [5, 6].

Normal biosynthesis of catecholamines (dopamine, norepinephrine, and epinephrine) occurs in the neuronal tuberosities. Tyrosine diffuses into the neuron and is taken up into storage granules containing tyrosine hydroxylase. This

enzyme converts the tyrosine to 3,4-dihydroxyphenylalanine. Further conversion by L-aromatic amino acid decarboxylase converts 3,4-dihydroxyphenylalanine to dopamine. Dopamine- β -hydroxylase converts dopamine to norepinephrine within synaptic storage vesicles. However, the enzyme dopamine- β -decarboxylase is not specific to dopamine and is also involved in the synthesis of serotonin from 5-hydroxytryptamine (5-HT) [7]. Epinephrine is created in the adrenal medulla by the same process except that norepinephrine diffuses out of the storage vesicle and is converted by phenylethanolamine-*N*-methyltransferase to epinephrine. It is then transported back into vesicles for release (see Fig. 2) [8, 9].

Norepinephrine is stored in the synaptic vesicles in high concentration along with ATP, chromogranin, and dopamine- β -hydroxylase. When norepinephrine is released, all of vesicle contents are released simultaneously. The effects of monoamine oxidase (MAO), which is an intracellular enzyme, and the high-affinity norepinephrine transporter protein keep the concentration of cytosolic norepinephrine low. On stimulation of a postganglionic sympathetic neuron, norepinephrine-containing vesicles are transported to the nerve membrane, where they fuse and release norepinephrine into the synaptic cleft. Neurotransmission is halted by reuptake of norepinephrine back into the presynaptic terminal or diffusion away from the synaptic cleft. Reuptake occurs by way of the norepinephrine transporter. This transporter has a high affinity for norepinephrine but also transports dopamine, tyramine, other monoamines, and other phenylethylamines such as amphetamine [10]. Although catechol *O*-methyltransferase (COMT) is present in the cleft, neurotransmission is halted mostly by reuptake and not by enzymatic degradation of the neurotransmitter (Fig. 3) [11, 12]. In addition to normal neurotransmission, the presence of other endogenous agents can alter neurotransmission by affecting prejunctional neuroreceptors (Fig. 4). These agents include adenosine triphosphate (ATP), opioids, and prostanoids. By altering ionic influx at the receptors, the nerve stimulation is affected (Table 3) [13].

Fig. 1 Graphic depiction of the structure–activity relationships among the catecholamines and related phenylethylamines

The central sympathetic nervous system predominantly uses norepinephrine, epinephrine, and dopamine as communicating neurotransmitters. The main noradrenergic nucleus is located in the cortical locus coeruleus. Its axons radiate into the cortex, cerebellum, and other structures. Norepinephrine released from the locus coeruleus into the hippocampal projections increases cortical neurologic activity through β -adrenergic receptor stimulation. Norepinephrine release into

the outer cortical area has an inhibitory effect mediated by α -receptor agonism. If the locus coeruleus receives a nonspecific stimulus, there is widespread cortical activation with excitation. This activation may be part of the reason why nonspecific sympathomimetics can cause an increase in hyperattentiveness and reduction in fatigue [14]. Stimulation of the locus coeruleus also affects serotonin, endogenous opioid, and acetylcholine neurotransmission by way of the

Fig. 2 Prejunctional and postjunctional sites of action of drugs that modify noradrenergic transmission at a sympathetic neuroeffector junction. L-Tyrosine is actively transported into the axoplasm of the neuron, where it is converted first to L-dopa by tyrosine hydroxylase (TH) and then to dopamine by aromatic L-amino acid decarboxylase (ALAAD). Dopamine is actively transported into synaptic vesicles, where it is converted by dopamine β-hydroxylase (DBH) to norepinephrine (NE). The arrival of a nerve action potential at the varicosity causes the influx of calcium ions, which promotes the exocytotic release of NE into the neuroeffector junction, where NE can activate receptors on postjunctional smooth muscle or glandular cells (α₁ or α₂) or cardiac cells (β₁) or on the prejunctional neuronal membrane (α₂). Activation of the α₂ receptor inhibits the further release of NE. The action of NE is terminated by transport back into the varicosity, uptake 1. In the varicosity, NE can

be stored in the synaptic vesicle or metabolized by monoamine oxidase (MAO) to inactive deaminated products. NE also is lost from the neuroeffector junction by diffusion and by transport into the postjunctional cell, uptake 2, where it is metabolized to normetanephrine by catechol O-methyltransferase (COMT). Drugs that enhance or mimic noradrenergic transmission (1) facilitate release (e.g., amphetamine), (2) block reuptake (e.g., cocaine), and (3) are receptor agonists (e.g., phenylephrine). Drugs that reduce noradrenergic transmission (1) inhibit synthesis (e.g., 1a, α-methyltyrosine; 1b, carbidopa; 1c, disulfiram), (2) disrupt vesicular storage (e.g., reserpine), (3) inhibit release (e.g., guanethidine), and (4) are receptor antagonists (e.g., phentolamine) (From Brody TM, Lamer J, Minneman KP [eds]: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, with permission)

medullary cholinergic neurons, opioid peptide neurons, and central raphe serotonin neurons that all penetrate the locus coeruleus [14, 15]. Dopamine neurotransmission is likewise altered by

endogenous opioids at the μ and κ receptors in the mesolimbic system [16]. This interplay gives the varied presentation of patients with a sympathomimetic syndrome.

Fig. 3 Adrenergic neuroeffector transmission; the termination of norepinephrine (NE) neurotransmission. MAO monoamine oxidase, COMT catechol *O*-methyltransferase

(From Brown OM: Adrenergic drugs. In Smith CM, Reynard AM [eds]: Textbook of Human Pharmacology. Philadelphia, WB Saunders, 1992, p 144, with permission)

Adrenergic Receptors

Noradrenergic receptors (Table 4) act as the binding site for sympathomimetic agents. Receptors are divided into ligand-gated ion channel receptors and G protein receptors. When an agent binds to a ligand-gated ion channel, the pore undergoes a conformational change and allows entry of a specific ion, which triggers secondary effects. G-linked proteins are coupled to cyclic guanosine triphosphatase (GTPase). Activation of these receptors leads to phosphorylation of the cyclic GTPase and a cascade of activities eventually altering the ionic flow. A sympathomimetic agent may affect ligand-gated ion channels, G protein receptors, or both. All adrenergic receptors are of the G protein type. Adrenergic receptors generally have been classified as α_1 , α_2 , β_1 , β_2 , and β_3 [18], and their receptor distribution is variable throughout the various organ systems. The ocular radial muscle is α_1 , but the ciliary body is predominantly β_2 . The heart contains β_1 and β_2 receptors. Arteries vary in their concentration of α_1 , α_2 , and β_2 , whereas the CNS has α_1 . The venous system has α_1 , α_2 , and β_2 receptors

[18]. Bronchodilation occurs from stimulation of β_2 receptors in the bronchiole smooth muscle [19].

Sympathomimetic agents stimulate adrenergic receptors in a number of ways. Sympathomimetic agents classified as direct agents bind directly to α and β receptors. For the most part, these agents do not cross the blood–brain barrier. Indirect sympathomimetic agents cause the release of cytoplasmic norepinephrine or dopamine without vesicular exocytosis. The neuronal membrane bidirectional transporter facilitates the uptake of many indirect-acting sympathomimetics, such as amphetamine and ephedrine, which normally would have problems crossing the bilipid membrane (Fig. 5) [20]. When the indirect-acting sympathomimetic has entered the cell, the agent is transported into a storage vesicle. Normal vesicular pH is 5.5, but indirect-acting sympathomimetics buffer the storage vesicle pH, reducing the pH gradient across the membrane, which causes the release of stored norepinephrine and dopamine into the cytoplasm. Release of norepinephrine is accompanied by a small amount of dopamine. As the cytoplasmic concentration of catechol increases, norepinephrine and dopamine compete with these indirect-acting sympathomimetic agents for the

Fig. 4 Prejunctional regulation at the sympathetic neuroeffector junction. The *left* varicosity illustrates autoinhibition of neurotransmitter release, including possible “lateral” inhibition (i.e., transmitter from one varicosity inhibiting release from an adjacent varicosity). The *right* varicosity illustrates prejunctional regulation of transmitter release by tissue and blood-borne chemicals. See Table 3 for a list of involved substances. Postjunctional receptors are shown as circles; prejunctional inhibitory

autoreceptors are shown as squares; prejunctional heteroreceptors are shown as triangles. ATP adenosine triphosphate, NE norepinephrine, NPY neuropeptide Y (From Fink GD: Regulation of blood pressure by the autonomic nervous system. In Brody TM, Larner J, Minneman KP [eds]: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, p 177, with permission)

transport back into the vesicle. The increased cytoplasmic catechol concentration facilitates reverse transport via the cytoplasmic norepinephrine transporter, to the extracellular synapse. The release of norepinephrine has an inhibitory effect on its own release through the presynaptic α_2 receptor; this occurs by inhibiting adenylate cyclase (Fig. 6 [21]). Inhibition of the transporter protein by tricyclic antidepressants abolishes amphetamine-induced norepinephrine release [6]. Nonpolar agents do not require the transporter to enter the cell but diffuse across the lipid bilayer [5]. Mixed-acting sympathomimetics can both indirectly cause norepinephrine release and directly stimulate adrenergic receptors. Neuronal uptake inhibitors can either competitively or noncompetitively inhibit biogenic amine uptake.

MAO and COMT inhibitors prevent catabolism of biogenic amines and increase cytosolic catechol concentrations. Finally, presynaptic α_2 antagonism interrupts normal feedback inhibition and increases sympathetic output.

Clinical Presentation

Central Nervous System (CNS)

The effects of sympathomimetics on the CNS are extensive, ranging from hyperpyrexia to mental status changes to seizures. Because projections from the locus coeruleus innervate most of the CNS, including the cerebral cortex, cerebellum,

Table 3 Prejunctional modulators of sympathetic neurotransmitter release

Chemical	Source	Receptor	Mechanism	Effect

From Fink [12]

and spinal cord, stimulation of this nucleus causes release of norepinephrine, leading to widespread cortical activation and excitation [22]. Indirect-acting sympathomimetics augment this excitation, increasing overall norepinephrine concentration; this explains the hyperattentiveness and lack of fatigue that accompanies the use of amphetamines, ecstasy (MDMA), and similar sympathomimetics [23]. Similarly many sympathomimetics cause concomitant dopamine release, which in turn activates the mesolimbic reward system and leads to euphoria, craving, addiction, and abuse potential. At the extreme end of the dopaminergic spectrum is the psychosis, repetitive/compulsive behaviors (“tweaking”), and marked agitation that can be seen with overdoses of these agents.

Additional behavioral effects attributed to sympathomimetic agent abuse can include CNS toxicity such as hemorrhagic strokes. Subarachnoid hemorrhage has been reported with the use of many agents including cocaine, methamphetamine, and MDMA [24–26]. This event is seen most frequently in individuals who have a preexisting cerebral aneurysm or arteriovenous malformation [27]. The transient but intense elevation in blood pressure that can be seen with cocaine use is enough to cause such defects to rupture [27]. The presence of methamphetamine predicts worse outcome in those who present with aneurysmal subarachnoid hemorrhages

[28]. Phenylpropanolamine (PPA) is an α -adrenergic sympathomimetic that formerly was available over the counter in the USA as a component of cold remedies and appetite suppressants [29]. In November 2000, the US Food and Drug Administration issued a public health advisory concerning the risk of hemorrhagic stroke in users of PPA and urged drug manufacturers to remove products containing PPA from the market. This advisory was prompted by the findings of the Hemorrhagic Stroke Project, which reported that use of PPA is an independent risk factor for hemorrhagic stroke in women [29] using these products as diet aids. Ephedra alkaloids, which were frequently sold over the counter as dietary supplements for weight loss or improved energy, have been linked only anecdotally to adverse cerebrovascular events [30]; the link has not been shown in a controlled trial. Regardless, the Federal Drug Administration banned the use of ephedra in dietary supplements in 2004 (<http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/2004/ucm108242.htm>).

In addition to hemorrhagic strokes, thrombotic strokes have been reported in association with cocaine use. An increased risk of these ischemic strokes has not been shown in a controlled trial. If stroke does occur, it has been hypothesized that α stimulation may cause vasoconstriction of large cerebral arteries, leading to thrombosis as a result

Table 4 Noradrenergic receptors

Receptor type	Effector	Response to stimulation
α_1	Arterioles (resistance vessels)	Constriction
	Veins	Constriction
	Uterus	Contraction
α_2	Presynaptic nerve ending	Inhibit NE release
		Vasodilation
	Postsynaptic CNS	Decreased sympathetic tone
	Pancreatic islets	Vasodilation
		Decreased secretion
β_1	Heart	Increased inotropy
		Increased chronotropy
β_2	Bronchioles	Dilation
	Arterioles	Dilation
	Metabolic sites	Enhanced metabolism (glycogenolysis and gluconeogenesis)
	Uterine smooth muscle	Relaxation
	Pancreatic islets	Increased secretion
β_3	Adipose tissue	Lipolysis
	Muscle	Thermogenesis
Dopamine	Mesenteric arterioles	Dilation (low dose)
		Constriction (high dose)

Data from Refs. [12, 17]
CNS central nervous system, NE norepinephrine

of stasis and sympathomimetic-induced platelet activation [31]. This hypothesis is questionable because these vessels lack endothelial α receptors.

Seizures may complicate sympathomimetic overdose. Massive cocaine overdose, such as seen in packet rupture in body packers, can lead to generalized tonic-clonic activity and status epilepticus. Seizures are considered a major indicator of cocaine-related lethality in humans [32]. The long-term neurologic sequelae of cocaine-induced seizures have been documented [33]. Seizures have been seen in individuals using relatively small amounts of cocaine [34]. Cocaine-related seizures may be relatively refractory to many standard anticonvulsants

Fig. 5 The mode of action of amphetamine, an indirect-acting sympathomimetic amine. Amphetamine enters the nerve terminal via the norepinephrine (NE) carrier (uptake 1) and enters synaptic vesicles via the vesicular monoamine transporter, in exchange for NE, which accumulates in the cytosol. Some of the NE is degraded by monoamine oxidase (MAO) within the nerve terminal, and some escapes, in exchange for amphetamine via uptake 1, to act on postsynaptic receptors. Amphetamine also reduces NE reuptake via uptake 1, enhancing the action of the released NE. VMAT, vesicular monoamine transporter (From Rang HP, Dale MM, Ritter JM, Gardner P: Pharmacology, 4th ed. New York, Churchill-Livingstone, 2001, p 158, with permission)

[35]. The refractoriness is related in part to the lack of knowledge of the precise mechanism by which cocaine causes seizures but may reflect a decrease in gamma-aminobutyric acid (GABA) sensitivity and an increase of N-methyl D-aspartate sensitivity. Most standard anticonvulsants alter membrane sensitivity and prevent seizure propagation whereas sympathomimetic-toxic patients may need specific GABAergic medications such as benzodiazepines or barbiturates. Although seizures can result from a single high dose of cocaine, there is evidence that repetitive administration of subconvulsive doses of cocaine

Fig. 6 Feedback control of norepinephrine (NE) release. The presynaptic α_2 adrenoceptor inhibits adenylate cyclase, reducing intracellular cyclic adenosine monophosphate (cAMP). cAMP acts to promote Ca^{2+} influx in response to membrane depolarization and to promote the release of norepinephrine and adenosine triphosphate (ATP) (From Rang HP, Dale MM, Ritter JM, Gardner P: Pharmacology, 4th ed. New York, Churchill-Livingstone, 2001, p 144, with permission)

can lead to a decreased seizure threshold, a phenomenon known as *pharmacologic kindling* [34, 36]. This feature, combined with the epileptogenic nature of cocaine, contributes to the significant neurologic impairment that can be associated with cocaine use.

In the CNS, cocaine causes an approximately threefold increase in D_3 binding sites in the locus accumbens and parts of the caudate and putamen, with upregulation of k_2 receptors in the amygdala. This activity can contribute to the hallucinations and aggressive and violent behavior seen in patients with cocaine overdoses [10, 16]. The pathophysiology of cocaine intoxication is described in ► **Chap. 75, "Cocaine."**

Psychiatric manifestations of sympathomimetic intoxication are common. Psychosis seems

to be more likely with amphetamines than cocaine, and once an amphetamine user experiences psychosis, it is likely to recur. These patients can be difficult to differentiate from a primary psychotic disorder based on presenting symptoms alone. Other neurological manifestations of sympathomimetic abuse include bruxism, euphoria, choreoathetosis, agitation, violence, and hallucinations.

Cardiovascular System

Cardiovascular manifestations are seen frequently with the sympathomimetic toxidrome. Because many of these agents have α -, β -, or mixed receptor agonism, the effects are varied. Agents with almost pure α effects, such as phenylpropanolamine, may cause isolated hypertension with reflex bradycardia. Hypertension from direct α agonism on the vasculature receptors results in significant vasoconstriction. Other agents, depending on the amount of β_1 or β_2 predominance, can cause hypotension from β_2 -induced vasodilation and β_1 -enhanced tachycardia. Generally, with the exception of patients intoxicated with the predominately α agents, patients present with tachycardia, dysrhythmias, and hypertension followed by, in the premonitory state, hypotension.

Sympathomimetics may cause coronary ischemia or infarction. Demand ischemia is the result of a mismatch between increased myocardial oxygen demand (hypertension and tachycardia) and supply (coronary blood flow). The significantly increased workload may be enough to cause ischemia in some sensitive individuals. Because cocaine is also a potent vasoconstrictor, it has the potential to exaggerate the mismatch between supply and demand. Cocaine has additional properties that promote intracoronary thrombosis by way of platelet activation and inhibition of clot dissolution, and long-term use may cause premature atherosclerosis [37, 38].

Dysrhythmias are a frequent and potentially lethal complication of sympathomimetic toxicity and occur through a number of mechanisms. β stimulation resulting in calcium entry into the myocytes and the subsequent elevation of the

resting potential enhances automaticity. Increased automaticity increases the potential for the generation of ectopic beats with the potential to degenerate into lethal dysrhythmias [39]. Some sympathomimetic agents, such as cocaine, can also affect cardiac ion channels and alter the duration of the action potential and the normal repolarization dispersion. Early after depolarizations in the setting of a prolonged action potential or prolonged JT interval from inhibition of I_{kr} can initiate ventricular tachycardia or torsades de pointes. For further discussion of dysrhythmogenesis caused by cocaine, see ► Chap. 75, “Cocaine.” Diseased areas of myocardium from contraction band necrosis serve as another potential nidus for arrhythmogenesis and loss of inotropy [40, 41].

Sympathomimetic-induced hyperthermia is multifactorial and a marker of significant toxicity. Amphetamines and MDMA activate the hypothalamic–pituitary axis and the sympathetic system and increase levels of circulating catecholamines, cortisol, and thyroid hormones. Endogenous heat production increases from a combination of increased psychomotor activity such as dancing and thermogenic brown fat activation via α_1 and β_3 stimulation. Concomitantly, norepinephrine-induced cutaneous vasoconstriction impairs heat dissipation. The resultant hyperthermia can lead to rhabdomyolysis, acidosis, and cerebral dysfunction. Mortality and severe outcomes are correlated with elevated temperatures in MDMA abusers and methamphetamine body stuffers [42, 43].

Renal System

The most significant renal-related side effect is acute kidney injury associated with rhabdomyolysis, which has been reported mostly for cocaine and the amphetamines. Renal injury can occur via several mechanisms. Prolonged seizures can lead to rhabdomyoglobinuric renal failure. Overdose-related coma with associated muscle compression also can cause rhabdomyolysis [44, 45]. Prolonged vasoconstriction of intramuscular arteries may contribute; it also is

hypothesized that cocaine has some direct toxic effects on skeletal muscle [44, 46, 47]. Rhabdomyolysis has been linked to sympathomimetic-induced hyperthermia resulting from a combination of centrally mediated processes, elevated ambient temperatures, peripheral vasoconstriction, indirect mitochondrial uncoupling, and prolonged dancing at ecstasy-driven rave parties [48]. Compartment syndrome is rare but has been reported in a case series of patients after ingestion of “bath salts” (cathinones) [49].

Renal failure has been reported without associated rhabdomyolysis [47]. This renal failure is believed to be secondary to renal vasculature vasoconstriction seen with cocaine abuse. Renal artery vasoconstriction can lead to ischemia and kidney infarction [45]. Additionally, chronic use of sympathomimetic drugs can lead to accelerated hypertension with associated renal failure [48].

Levamisole is a veterinary antihelminthic agent that had previously been used as an immunomodulatory therapy. Since 2003, levamisole has been increasingly identified as a “cutting” agent in cocaine due to its physical characteristics and the possibility that it adds to the euphoric effects of cocaine via multiple mechanisms. Reports of unintentional levamisole toxicity are increasing, and commonly one or more of the following have been associated with levamisole: leukopenia and agranulocytosis, thrombocytopenia, vasculitis, cutaneous necrotizing vasculitis (similar to warfarin induced), and multifocal inflammatory leukoencephalopathy [50].

Diagnostic Studies

The laboratory diagnosis is nonspecific. Patients may show secondary evidence of adrenergic excess with hypokalemia, hypomagnesemia, hyperglycemia, and leukocytosis without left shift. If the patient has a significant sympathomimetic syndrome, is hyperpyrexia, or shows evidence of prolonged muscle activity, there may be an associated lactic acidosis [51]. Ketonuria may be present if the patient has been using a sympathomimetic for a prolonged period without eating or if there is evidence of metabolic hyperactivity

and lipolysis. The electrocardiogram most often shows sinus tachycardia, but paroxysmal supra-ventricular tachycardia or other tachydysrhythmias may be present. Routine radiographic studies are not helpful unless there is suspicion of body packing or body stuffing.

Differential Diagnosis

It may be difficult to distinguish between a true sympathomimetic syndrome and many other overdoses and conditions (Tables 5 and 6). In particular, ethanol and sedative-hypnotic withdrawal may present with all of the same signs and symptoms, including mental status changes and seizures. In many respects, this could be considered an endogenous sympathomimetic syndrome because withdrawal causes a large release of catecholamines and creates the same physiologic state [51].

Anticholinergics tend to present with their own stereotypical syndrome that can be differentiated with careful observation and examination of the patient (see Table 6). In our experience, the anticholinergic toxidrome leads to mydriasis with cycloplegia, dry mucous membranes, tachycardia (but not usually as fast as seen with sympathomimetics), hypertension, hyperpyrexia, and tachypnea, usually in contrast to the extremes seen with sympathomimetics. Key differentiation points are loss of compensatory sweating, absence of bowel sounds, urinary retention, and red flushed skin in anticholinergic poisoning. The mental status change also is different. Patients with an anticholinergic toxidrome are nonfocally agitated, with picking motions of their hands. Their mouths appear cottony, and they answer with slurred, nearly incomprehensible speech. Many patients, when lying quietly, appear to be listening to internal voices. Treatment with antipsychotics that antagonize muscarinic receptors, such as many of the atypical second-generation agents, may enhance toxicity, and benzodiazepines may not be effective unless very large doses are used [52]. Physostigmine reorients the anticholinergic patient, restores vital signs toward normal, and confirms the diagnosis. The patient

Table 5 Differential diagnosis of sympathomimetic syndrome

Toxic
Anticholinergics (antihistamines, scopolamine, atropine, hyoscyamine, hydroxyzine)
Serotonin syndrome
Neuroleptic malignant syndrome
MAO inhibitor intoxication
Strychnine poisoning
Drug interactions (MAO inhibitor plus meperidine, lithium, or haloperidol)
Salicylates
Pentachlorophenol
Cyclic antidepressants
Lithium intoxication
Metabolic
Ethanol withdrawal
Sedative-hypnotic withdrawal
Thyrotoxicosis/thyroid storm
Status epilepticus
Heatstroke
Hypertensive encephalopathy
Hypoglycemia
Malignant hyperthermia
Infectious
Sepsis
Meningitis
Structural
Brain tumor
Pheochromocytoma

with a sympathomimetic syndrome may be nonfocally agitated and restless but constantly in motion, requiring significant restraint. Benzodiazepines in appropriate dosing can be useful [53, 54].

The neuroleptic malignant syndrome (NMS) and serotonin syndrome may present in what appears to be similar to a sympathomimetic toxidrome. In NMS, there is evidence of dopamine depletion or a central D₂ receptor block with decrease in dopaminergic activity in the CNS striatum and hypothalamus. This situation leads to disrupted core temperature regulation and hyperthermia, enhanced centrally mediated muscle activity with rigidity, increased sympathetic tone and autonomic instability, and a change in mental status. To be diagnosed with NMS, patients currently must be taking or recently

Table 6 Differential diagnostic features of stimulant syndromes

	BP	HR	Temperature	MS	Skin	Pupils	Special features
Sympathomimetic syndrome	↑	↑	↑	Altered	Diaphoretic	↑	Normal bowel sounds, reactive mydriasis
Alcohol/sedative-hypnotic withdrawal	↑	↑	Normal to ↑	Altered	Piloerection	↑	History of alcohol or sedative-hypnotic abuse, reactive mydriasis
Anticholinergic syndrome	↑↓	↑	↑	Altered	Dry	↑	Hypoactive bowel sounds, urinary retention, unreactive mydriasis
Complex status epilepticus	↓↑	Unreactive	Normal to ↑	Altered	Normal	Normal	Involuntary repetitive movements, unreactive pupils
Heatstroke	↓	↑	↑	Altered	Dry/hot	Normal	Core temperature >105 °F, history of exposure
Hypertensive encephalopathy	↑	↑ or ↓	Normal	Altered	Normal	Normal	Visual changes, papilledema, headache
Hypoglycemia	Normal	↑	Normal or ↓	Altered	Diaphoretic	Normal to ↑	Resolves with glucose
Meningitis	Normal or ↓	↑	↑	Altered	Normal to hot	Normal	Meningismus, headache
Neuroleptic malignant syndrome	Labile	Labile	↑	Altered	Normal to diaphoretic	Normal to ↑	Skeletal muscular rigidity, history of neuroleptic use
Serotonin syndrome	Labile	↑	Normal to ↑	Altered	Diaphoretic	↑	History of serotonin agent, myoclonus, shivering, hyperreflexia
MAO inhibitor	Labile	↑↓	↑	Altered	Diaphoretic	↑	History of MAO inhibitor agent, wide swings in vital signs with use of pressors, tremor, myoclonus
Cyclic antidepressants	↓	↑	Normal to ↑	Altered	Dry/flushed	↑	Widened QRS, R wave in aVR, and S wave in I, II
Pheochromocytoma	↑	↑	Normal	Normal to altered	Flushed	Normal	Paroxysms of hypertension and tachycardia
Sepsis	↓	↑	↑↓	Altered	Cool/clammy or hot/dry	Normal	Source of infection may be evident, low peripheral vascular resistance
Thyrotoxicosis	↑↓	↑	↑	Altered	Normal	Normal	Thyromegaly or tender thyroid, tachycardia disproportionate to fever

BP blood pressure, HR heart rate, MS mental status

have been taking a neuroleptic or another antidopaminergic medication and satisfy several additional criteria including increased core temperature, lead-pipe rigidity, autonomic instability, elevated creatine kinase, and change in mental status [55]. The chapter on NMS discusses this syndrome in more detail. By contrast, in the serotonin syndrome, there is primarily an excess of

5-HT_{2A} receptor stimulation, with a probable lesser contribution from effects at the 5HT_{1A} receptor. These patients have less remarkable extremity rigidity, but they should have the triad of altered mental status, autonomic dysfunction, and neuromuscular abnormalities. The neuromuscular findings are myoclonus, shivering, tremor, and hyperreflexia. In addition, patients may have

fever, incoordination, diaphoresis, and diarrhea. The patient may be on a single serotonin agent, on a series of agents, or overdosed on a serotonin agent [56, 57]. The serotonin syndrome is described in ► Chap. 24, “Serotonin Syndrome.”

Most serious MAO inhibitor overdoses involve agents that irreversibly inhibit MAO, the enzyme responsible for deaminating biogenic amines, leading to an increased availability of these amines in the cytosol. The patient may present with an initial asymptomatic phase, possibly with headache, and then develop neuromuscular excitation and evidence of enhanced sympathetic stimulation. The patient then becomes diaphoretic, agitated, hyperthermic, hyperreflexic, rigid, and tremulous and may develop myoclonus and seizures. Central nervous system depression, cardiac dysrhythmias, and cardiovascular collapse may follow. These patients are exquisitely sensitive to indirect-acting agents and may show wide autonomic instability if pressors are used [58]. The MAO inhibitor overdose may mimic serotonin syndrome but with rigidity, which may be lead pipe, particularly in the lower extremities; the patient also develops evidence of profound autonomic collapse [59, 60]. The reader is referred to ► Chap. 50, “Monoamine Oxidase Inhibitors” for a more complete discussion.

Patients with heatstroke may present with a high core temperature, tachycardia, altered mental status, tachypnea, and some muscular rigidity. Heatstroke is caused by loss of normal thermoregulation under some amount of heat stress. Patients may appear to be extremely toxic with a sympathomimetic syndrome, and differentiation may not be possible initially. The heatstroke patient initially may be diaphoretic and hypertensive but eventually becomes hypovolemic and hypotensive with dry skin. Multiple organ system failure then ensues. Treatment is the same as with the sympathomimetic syndrome, with supportive care and rapid cooling. The actual diagnosis may not be determined until after resolution of the acute event [61].

Malignant hyperthermia occurs in patients with abnormalities in their muscular excitation–contraction mechanisms. These

patients present with tachycardia and central hyperpyrexia. Differentiation from sympathomimetic syndrome is helped by a family history of similar events or temporally related exposure to general anesthesia or similar agents. The patients always have muscular rigidity and usually are sweating [61]. Additional discussion of this syndrome can be found in ► Chap. 29, “Malignant Hyperthermia.”

Diagnostic Studies

Certain studies may help in the differential diagnosis. Although leukocytosis is present in most sympathomimetic states, septic patients should show a left shift with other evidence of infection, such as toxic granules, Döhle’s bodies, or leukopenia. In thyrotoxicosis, thyroid-stimulating hormone is markedly depressed. In hypoglycemic patients, serum glucose is less than 70 mg/dL (3.89 mmol/L). Urinary collection of vanillylmandelic acid helps differentiate pheochromocytoma.

The electrocardiogram may be useful in differentiating neuroleptic agents and cyclic antidepressants from other causes. Most neuroleptics cause a nonspecific widening of the QT_c. Classic cyclic antidepressants frequently show a rightward deviation of the terminal 40 msec of the frontal plane QRS (an R wave in aVR and an S wave in I, II) and QT_c and QRS prolongation (Fig. 7).

A computed tomography scan of the head is useful to rule out CNS bleeding or mass. In the case of pheochromocytoma, computer tomography or magnetic resonance imaging of the abdomen and adrenals may identify the culprit lesions.

Toxicologic screening may identify some of these agents and help with differentiating toxic causes. Specific testing for lithium and salicylates is available. The most common immunoassay tests for sympathomimetic drugs of abuse such as amphetamine, methamphetamine, and cocaine. Since the immunoassay is a class assay and is predicated on the phenethylamine structure, these tests are fraught with many false-positive and false-negative results. For example, because

Fig. 7 A classic electrocardiogram from a tricyclic antidepressant-poisoned patient, showing sinus tachycardia, QTc and QRS prolongation, elevated R wave in aVR,

and S waves in I, II. This ECG would be highly suggestive of any fast inward sodium channel blocker toxicity

there is structural similarity to ephedrine and pseudoephedrine, the test may show a false-positive amphetamine result for these agents. Amphetamine derivatives, including cathinones and drugs such as MDMA, may not be detected when present and result in a false-negative result. These assays are not useful for anticholinergic agents and other serotonergic amphetamines or cathinone derivatives. Assays for tricyclic antidepressants identify a shared central seven-membered ring and will detect the classic cyclic antidepressants as well as agents sharing a similar structure, such as quetiapine. Beta-adrenergic agents, MAO inhibitors, and neuroleptics are not recognized by these immunoassays. Comprehensive thin-layer chromatography coupled with immunoassay, high-performance liquid chromatography, and gas chromatography–mass spectroscopy may identify many compounds. However, even with the high sensitivity and specificity of these diagnostics, newly synthesized xenobiotics may go undetected. A negative toxicologic screen does not exclude the presence of a particular xenobiotic and may represent poor assay selectivity or an insufficient quantity of the xenobiotic.

Treatment

Because sympathomimetic toxicity reflects a general increase in catechol effect, treatment is directed toward attenuating this pathway. The simplest and most efficient way is to depress the CNS release of catecholamines with benzodiazepine or barbiturate sedation [62, 63, 64] (Grade I recommendation) which decreases norepinephrine release. Administration of nitrates is beneficial in the management of some sympathomimetic effects such as cocaine-induced chest pain, coronary artery vasospasm, and hypertension [17, 65–67] (Grade I evidence). While the safe use of combined α and β -blockade with agents such as carvedilol or labetalol has been substantiated in small trials [68, 69] and is recommended by the American Heart Association as second-line agent considerations after nitroglycerin and calcium channel blockers for suspected ACS in cocaine and methamphetamine users [70], the use of beta-blockers without alpha antagonist activity, until further evidence emerges, should be avoided. Alpha antagonism may also help attenuate severe hyperthermia in MDMA toxicity (Grade 1)

[71, 72]. Tachydysrhythmias usually respond to sedation (Grade I evidence), but a calcium channel blocker may be required. Evidence demonstrating a consistent benefit of calcium channel blocker administration to patients with sympathomimetic toxicity is lacking but is a class I (Grade C) recommendation for cocaine and methamphetamine users with ischemic chest pain by the AHA (class I) [64, 70]. Peripheral alpha-adrenergic antagonists (phentolamine) and central alpha₂ agonists should also be considered to control severe hypertension either primarily (class I) or when benzodiazepines and nitroglycerin fail (class III). In general, most antidysrhythmics should be avoided since many sympathomimetic agents have sodium channel attenuating properties (e.g., cocaine) and may have additive toxicity. In the setting of QRS widening or wide complex tachycardias from cocaine, hypertonic sodium bicarbonate should be strongly considered (class I) [73]. Because sympathomimetics can induce platelet aggregation, aspirin therapy in the presence of cardiac-type chest pain is suggested [74] (Grade I evidence). Hyperpyrexia must be treated aggressively with rapid cooling and prevention of muscle hyperactivity since, at least with serotonin toxicity, mortality is directly correlated with core body temperature [43, 75]. Little evidence exists to suggest an optimum technique for cooling patients with drug-induced hyperthermia and this recommendation is derived from the benefits seen with aggressive cooling in exertional heatstroke (Grade III evidence) [76]. Sedation may be helpful, but if the patient has rigidity, marked myoclonus, or prolonged seizure activity, paralysis with a nondepolarizing agent, in addition to sedation, may be necessary to halt the continued lactic acidosis and heat production. Psychomotor agitation usually responds to sedation with a GABAergic agent such as a benzodiazepine or propofol (Grade III evidence), and seizures generally are brief and should also respond to benzodiazepines. If continued seizures develop, an anticonvulsant such as a barbiturate (e.g., phenobarbital 260 mg IV initial dose) is suggested [77, 78].

Special Populations

Patients who take β -blockers may not present with the tachycardia associated with the sympathomimetic syndrome. If there is a significant α component to the sympathomimetic agent, the patient may present with exaggerated hypertension from the unopposed α effect. Pediatric patients comprise a bimodal distribution of sympathomimetic toxicity. Younger patients tend to have accidental ingestions and usually present with smaller, self-limited sympathomimetic toxicity. Treatment is the same as adults except the medication doses are weight dependent. Adolescents tend to use larger doses or may “stack” the hallucinogenic amphetamines resulting in a more intense and prolonged toxicity. These patients can present extremely ill and markedly hyperthermic with multisystem organ failure. High doses of benzodiazepines, active external cooling, and aggressive attention to detail are all necessary for a good outcome.

Drug reactions that lead to an intensive medical response represent a significant medical problem. These reactions can be due to known pharmacologic activities of a drug, activation of the immune system, or other mechanisms. Reactions that involve the immune system account for only 10% of cases but can be dramatic and life-threatening [1, 2]. The cost of drug reactions with an immunologic basis is approximately \$3 to \$13 billion/year, when extrapolated from estimates of the cost for all drug reactions in the United States [1, 3]. Reactions that involve immunologic mechanisms often are described as “allergic.” The word *allergic* is used to describe reactions that are mediated through the IgE class of antibodies. The term *immunologic drug reaction* includes any immune reaction that involves specific recognition by the immune system (via antibodies or the T-cell receptor) and thus includes IgE-mediated reactions [4]. The term *pseudoallergic* often is used to refer to drug reactions that mimic allergic reactions (e.g., release of proinflammatory mediators) but occur via activation of the immune system in a fashion that is independent of antibody or specific receptors [4–7]. The term *idiosyncratic* refers to an uncharacteristic response to a drug that is qualitatively different from its pharmacologic activity and that is not immunologic in mechanism. These reactions may be genetically based and related to metabolic or enzyme deficiencies [4, 5].

History

At the end of the nineteenth century, there were dramatic advances in the use of inoculation of killed or attenuated organisms to prevent human infectious diseases, including smallpox, rabies, typhoid, cholera, and plague [8]. Two immunization strategies led to paradoxical reactions and inadvertently expanded our understanding of the immune system. In the first approach, animals were given injections of increasing doses of a toxin in an attempt to protect them from subsequent exposure. The second approach was to protect or treat humans with sera from animals that had been injected previously with infectious agents or toxins.

The importance of these unexpected reactions was first appreciated by Richet, who immunized dogs with sea anemone toxin with the objective of eventually treating Mediterranean Sea bathers stung by jellyfish [9–11]. Richet hypothesized that animals surviving a sublethal dose would be protected against subsequent stings. However, when given a subsequent dose of similar or smaller size, some of the dogs died within minutes. Reaction symptoms on rechallenge were considerably different from the subacute toxic reaction progressing over 4 or 5 days seen after the initial injections. Reactions to rechallenge were characterized by the rapid (within minutes) onset of breathing problems, lethargy, and diarrhea. Richet concluded that the first injections of toxin had not prophylaxed the dogs but rather had changed the animals into a state of anaphylaxis (without protection) [10, 12–14].

Reactions to heterologous (from another species) blood products were appreciated in 1667 after early attempts to use lamb's blood for transfusion [15]. The desire to treat human infectious diseases with sera from immune animals led to efforts to understand these reactions. In the early years of the twentieth century, antiserum developed in horses, particularly anti-diphtheria antitoxin, came into general use and was associated with 38 reported fatal reactions and many more nonfatal reactions between 1895 and 1923 [15]. Some of these reactions occurred

immediately and were similar to the reactions Richet observed in dogs, but most evolved more slowly with different manifestations. In 1905, Von Pirquet and Schick coined the term *serum sickness* to describe this latter reaction, characterized by fever, arthritis, and erythema multiforme occurring 7–10 days after exposure to heterologous serum [15]. During the next decade, the overlap between anaphylaxis and serum sickness became apparent, and the concept of different manifestations of “hypersensitivity” came to be appreciated. As medical care evolved during the twentieth century, therapy with heterologous serum gave way to the use of antibiotics and recognition of allergic reactions to these new agents. Immunologic reactions to antibiotics continue to be a substantial problem, and a plethora of drugs generated for a variety of illnesses have become important sensitizing substances. Most recently, the development of monoclonal antibodies has emerged as a novel source of sensitization.

Pathophysiology

Reactions to drugs vary widely. Some reactions are limited to the skin or to specific internal organs; others are systemic. Although some agents cause stereotypical reactions, almost any agent can cause any type of reaction. In the 1960s, Gel and Coombs characterized immunologic reactions by the major immunologic process operative in a reaction [4]. In this analysis, type 1 reactions are immediate hypersensitivity reactions involving cross-linkage of IgE bound to high-affinity receptors on mast cells or basophils. Type 2 reactions are due to cytotoxic antibodies. Type 3 reactions are due to immune complexes, and type 4 reactions are due to cell-mediated hypersensitivity. Adkinson described this concept for penicillin reactions (Table 1) [4]. Although this process is a useful method of discussing immunologic reactions to drugs, more recent data have shown that there is marked overlap among these arms of the immune system such that several of the Gel- and Coombs-type reactions can occur in a single reaction. A different approach that is more

functional is to classify reactions to drugs based on the timing and predominant clinical manifestation (Table 2) [2, 16].

Many drugs are small, immunologically inactive molecules, such as penicillin, that activate the immune system by virtue of their ability to “haptenate” naturally occurring plasma and cellular proteins. The process of forming haptens is fairly well understood for penicillin and probably is similar for other small molecules (Fig. 1). In this scenario, the drug itself is not recognized by the immune system because of its small size (molecular weight 100–1000 days). When the drug or its metabolic product is bound to a protein, it distorts the three-dimensional structure of the protein so that the drug, now presented as part of a protein, is recognized as a novel structure leading to clonal expansion of T cells. T cells interact with B cells and produce cytokines that also drive the maturation of B cells. These maturing B cells express surface immunoglobulin for the drug, then form plasma cells that secrete immunoglobulins that recognize the drug with high affinity [17]. Susceptible patients undergo class switching from an IgG response to produce IgE that binds to the high-affinity receptor for IgE (FcεRI) on mast cells and basophils, sensitizing these patients. Subsequent exposure to the “haptened” protein during a

Table 2 Classification of immunologic drug reactions based on their timing

Reaction type	Time of onset	Clinical manifestation
Immediate	<1 h	Anaphylaxis Angioedema Urticaria Bronchospasm
Delayed	>1 h, typically >6 h or several days	Morbilloform rash Interstitial nephritis Hemolytic anemia Thrombocytopenia Neutropenia Drug fever Stevens-Johnson syndrome Toxic epidermal necrolysis
	1–3 weeks	Serum sickness
	1–12 weeks	Drug reaction with eosinophilia and systemic symptoms (DRESS)

Modified from Refs. [2, 16]

Fig. 1 Generation of haptens. SC side chain (From Ref. [4])

repeat course of therapy leads to cross-linking of the antigen-specific IgE bound to FcεRI, then to degranulation of mast cells and basophils [1, 4]. This process also can occur during a single course of drug therapy in which either the first

exposure was not appreciated or the initial sensitization and the effects of sensitization occur in rapid sequence [18].

The most limited reactions that are clearly IgE mediated manifest as diffuse urticaria (hives), but reactions can be generalized and include angioedema (of lips, tongue, and uvula), respiratory compromise (bronchospasm/wheezing, stridor, hypoxemia), gastrointestinal symptoms (abdominal cramping, vomiting), and vascular collapse [19]. It is unknown why only some patients produce IgE and why the reactions are to certain agents and not to others. Lack of a history of previous allergic reactions to drugs or to other allergens is not helpful. Some patients with a history of allergic reactions to drugs are prone to reactions with structurally unrelated medications [2]. This situation may be due to a genetic predisposition to recognize haptens; however, a history of allergic disease, such as allergic rhinitis, does not predispose to allergic drug reactions [1, 2]. Multiple drug hypersensitivity syndrome (MDH) may be due to derangements of T-cell function, as this is more common in delayed reactions, specifically severe cutaneous adverse reactions like drug reaction with eosinophilia and systemic symptoms (DRESS), also called drug-induced hypersensitivity syndrome (DiHS) [20].

Foreign molecules (antigens) can activate the immune system in a highly specific fashion. The molecules of the immune system that recognize antigens are either soluble proteins called *antibodies* or receptors on the surface of T cells (T-cell receptors) and B cells (B-cell receptors). Antibodies fall into five distinct molecular groups (in order of predominance in the circulation): IgG, IgM, IgA, IgD, and IgE. Antigens that lead to an IgE response are called *allergens*. Antibody molecules have two critical regions – the Fab region, which binds avidly to unique structures (antigens), and the Fc region, which binds to Fc receptors on effector cells. The IgG antibodies (normal range, approximately 700–1500 mg/dL [7–15 mg/mL]) account for the greatest portion of the humoral (soluble) immune response to foreign proteins. They participate in immune reactions by forming immune complexes with antigen or

by combining with Fc receptors on effector cells. IgE antibodies (normal range, approximately 0–250 ng/mL [0–0.25 mg/L]) are present at the lowest concentration, participate in host defense against parasites, and are responsible for immediate hypersensitivity reactions. IgE antibodies sensitize mast cells and basophils by binding with high affinity to FcεRI receptors. The process of antigen presentation by antigen-presenting cells (typically B cells, macrophages, and dendritic cells), immune recognition of T-cell epitopes (the component of an antigen recognized by the immune system) by T cells via the T-cell receptor, T-cell-mediated and antigen stimulation of B cells, maturation of B cells to become IgE-producing plasma cells, and sensitization of mast cells by IgE is illustrated in Fig. 2 [21]. IgE, bound to FcεRI and cross-linked by a specific antigen, causes degranulation of these cells with the rapid (0–30 min) release of potent vasoactive and proinflammatory mediators, such as histamine, leukotriene C₄, and prostaglandin D₂ [22]. T cells recognize a specific antigen by virtue of T-cell receptors (TCRs) that identify the unique specificity of a foreign peptide sequence in the context of the major histocompatibility loci [21]. A crucial precept of modern immunology is that the region of a foreign epitope recognized by the TCR is distinct from that recognized by the B-cell receptor and circulating antibodies [21].

Examples of IgE-mediated reactions are generalized anaphylaxis and more limited reactions, such as some cases of acute asthma, hives, and allergic rhinitis. IgG antibodies are responsible for more delayed adverse reactions, interacting with the immune system via Fcγ receptors (receptors for the Fc portion of IgG) and by forming soluble immune complexes. Immune complexes often activate the complement cascade, generating immunologically active complement fragments. Examples of IgG-mediated immunologic reactions include serum sickness and immune complex glomerulonephritis. Specific antigen receptors on T cells (T-cell receptors) have the ability to recognize foreign material in much the same way as antibodies do. This recognition leads to expansion and activation of clones of T cells.

Fig. 2 Sequence of events in immediate hypersensitivity reactions. Immediate hypersensitivity diseases are initiated by the introduction of an allergen, which stimulates IL-4 producing helper T cell responses and IgE production. IgE sensitizes mast cells by binding to FcεRI, and subsequent

These reactions generally are referred to as *delayed-type hypersensitivity* reactions. The most familiar example is the dermatitis seen secondary to poison ivy, but delayed-type hypersensitivity reactions also are seen with topical medications, such as neomycin, and can be seen in dermatologic reactions to systemically administered drugs [1, 23].

Drug Reactions

Anaphylaxis

The most terrifying reaction to an exogenous agent is anaphylaxis. These reactions are typically observed within the first 30 min after parenteral administration of the offending agent but can occur minutes to hours after the ingestion of a food [14, 24]. Typically the patient has a brief prodrome of anxiety and a sense of impending doom followed by cutaneous reactivity (generalized urticaria, itching or flushing, swelling of lips/tongue/uvula), respiratory compromise (bronchospasm/wheezing, stridor, hypoxemia), gastrointestinal symptoms (abdominal cramping, vomiting), hypotension, or vascular collapse [19]. Not all of these signs and symptoms need be present. For example, approximately 15% of patients with cardiovascular collapse due to anaphylaxis do not have cutaneous signs. Specific criteria for the diagnosis of anaphylaxis have been determined (Table 3).

IgE-Dependent Anaphylaxis

Cross-linkage of IgE-FcεRI complexes on mast cells and basophils initiates the most common form of anaphylactic reaction – IgE-mediated anaphylaxis. For this reaction to occur, the patient generally has been exposed previously to the agent, and some time (weeks to months) has passed to allow for the production of sufficient

Fig. 2 (continued) exposure to the allergen activates the mast cells to secrete the mediators that are responsible for the pathologic reactions of immediate hypersensitivity (From Ref. [21])

Table 3 Clinical criteria for diagnosing anaphylaxis (World Allergy Organization)

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:
1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized urticaria, itching or flushing, swollen “lips-tongue-uvula”) AND AT LEAST ONE OF THE FOLLOWING: A. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia) B. Reduced blood pressure or associated symptoms of end-organ dysfunction (e.g., hypotonia (collapse) syncope incontinence)
2. Two or more of the following that occur rapidly after exposure to a <i>likely</i> allergen ^a for that patient (minutes to several hrs) A. Involvement of the skin-mucosal tissue (e.g., generalized urticaria, itch-flush, swollen lips-tongue-uvula) B. Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia) C. Reduced blood pressure or associated symptoms (e.g., hypotonia (collapse), syncope, incontinence) D. Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced blood pressure after exposure to <i>known</i> allergen ^b for that patient (minutes to several hours) A. Infants and children: low systolic blood pressure (age specific) or greater than 30% decrease in systolic blood pressure ^c B. Adults: systolic blood pressure of less than 90 mmHg or greater than 30% decrease from that person’s baseline a) Or other trigger, for example, immunologic but IgE-independent or nonimmunologic (direct) mast cell activation b) For example, after an insect sting, reduced blood pressure might be the only manifestation of anaphylaxis; or, in a similar example, during allergen immunotherapy, after injection of a known allergen for that patient, generalized urticaria (only one body organ system affected) might be the only initial manifestation of anaphylaxis c) Low systolic blood pressure for children is defined as less than 70 mmHg from 1 month to 1 year, less than (70 mmHg, age 2) from 1 to 10 years, and less than 90 mm Hg from 11 to 17 years. Normal heart rate ranges from 80 to 140 beats/min at age 1–2 years, from 80 to 120 beats/min at age 3 years, and from 70 to 115 beats/min after age 3 years. Infants are more likely to have respiratory compromise than hypotension or shock, and in this age group, shock is more likely to be manifest initially by tachycardia than by hypotension

Modified from Ref. [19]

IgE to sensitize mast cells and basophils. Systemic anaphylaxis can be caused by a wide variety of agents. Many drugs are of such small molecular weight that they by themselves are not recognized by the immune system. Penicillins are the best-studied example of this type of drug. In this case, it is the drug bound to a large-molecular-weight protein (i.e., albumin) that becomes antigenic. In this situation, the drug is called a *haptén*.

In the hospital, a large array of drugs can precipitate IgE-dependent anaphylaxis, particularly antibiotics, neuromuscular blocking agents, and some reactions to nonsteroidal anti-inflammatory drugs (NSAIDs). Other substances may also trigger IgE-dependent anaphylaxis, including blood transfusions, foods, latex, and intravenous contrast material. In the operating room, some of the abovementioned warning signs may not be evident, and resistance to ventilation or vascular collapse may be the first sign of anaphylaxis. In the outpatient setting, patients can have IgE-dependent anaphylaxis as a result of food, insect stings, medications, or latex, as a

manifestation of systemic mastocytosis, and spontaneously idiopathic anaphylaxis.

IgE-Independent Anaphylaxis

Some agents cause a syndrome of anaphylaxis through an immunologic mechanism, but without involvement of IgE. These reactions were historically called *anaphylactoid reactions*, but more recently have been categorized as IgE-independent anaphylaxis. They are caused by direct mast cell activation, leading to symptoms that may be clinically indistinguishable from IgE-dependent anaphylaxis. Common causes of IgE-independent anaphylaxis include IV radio-contrast media, NSAIDs, opioids, dextrans (high molecular weight iron and colloids), and some monoclonal antibodies [19]. Intravenous radio-contrast material is thought to cause activation and degranulation of mast cells by virtue of its hyperosmolality. *N*-acetylcysteine can cause a similar syndrome, although the mechanism is even more obscure [25]. These can manifest just as severely as IgE-dependent anaphylaxis, and

treatment of both types of anaphylaxis is similar, with prompt use of epinephrine and removal of the offending agent.

Serum Sickness

The best-described non-anaphylactic systemic reaction is serum sickness. This reaction is characterized by fever, malaise, and a pruritic rash that is urticarial or maculopapular. Associated findings may include arthritis, proteinuria (rarely with frank glomerulonephritis), gastrointestinal symptoms, adenopathy, vasculitis, and peripheral neuropathy [26, 27]. Typically symptoms occur between 1 and 3 weeks from the initial exposure. However, if a prior exposure has occurred, symptoms can present more rapidly (within 12–36 h). This type of reaction is thought to be due to circulating immune complexes. Drugs commonly implicated in serum sickness include antibiotics (penicillin, sulfonamides, cefaclor in children), antiepileptics, NSAIDs, and thiazides. Some monoclonal antibodies and blood products can also cause serum sickness. Heterologous proteins commonly precipitate serum sickness, and these include antivenin (e.g., Crotalidae polyvalent and Crotalidae polyvalent immune Fab), digoxin immune Fab, and antithymocyte globulin [27, 28].

Drug Fever

The cause of drug fever is unknown, and it can be seen with many drugs, although β -lactam antibiotics are commonly implicated [29]. Drug fevers have a median onset of 7–10 days after initiation of the culprit medication, and this time interval is typical of antimicrobial-induced drug fever. However, intervals vary depending on the class of the culprit medication, with median onset of fever 0.5 days after initiation of antineoplastic drugs and 16 days with CNS agents [29]. It may be associated with eosinophilia, leukocytosis, and an elevated erythrocyte sedimentation rate, but it most frequently presents as an isolated symptom and poses a diagnostic dilemma. Because drug

fevers usually resolve within 48–72 h of stopping the drug, this forms a useful diagnostic test, although this is ultimately a diagnosis of exclusion [1].

Reactions with a Predominant Organ Involvement

Cutaneous reactions can occur with almost any drug taken systemically and vary from relatively benign to severe life-threatening lesions with morbidity similar to that seen with severe burns.

Urticaria and Angioedema

Diffuse urticaria or angioedema is due to degranulation of cutaneous mast cells. Although usually this is a self-limited process, urticaria and angioedema are severely distressing to the patient. This should be considered to be a systemic (not local) reaction and may be a harbinger of a more severe generalized reaction that is developing over time. If compromise of the airway is present, it must be treated aggressively. Angiotensin-converting enzyme inhibitors cause angioedema by virtue of their ability to inhibit important esterases, leading to excessive levels of vasoactive kinins (e.g., bradykinin). The localization of this swelling to the upper airway is not understood. Agents that can activate cutaneous mast cells by non-IgE-mediated mechanisms and cause symptoms of erythema, pruritus, dermatitis, or urticaria include radiocontrast media, vancomycin, *N*-acetylcysteine, opiates, amphotericin, tubocurarine, and physical stimuli, such as sunlight, pressure, vibration, heat, and cold. By virtue of location of the exposure or the presence of specific receptors, many of these agents most often activate only cutaneous mast cells, but more severe systemic reactions do occur [1, 4, 6].

Severe Cutaneous Adverse Reactions (SCAR)

Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN)

Erythema multiforme appears as raised erythematous lesions predominantly on the extremities with varied shapes, including target lesions, maculopapular rashes, urticaria, and vesicles. In most patients, infection or exposure to drugs or

both are thought to be responsible [1, 30]. Erythema multiforme minor is an acute, self-limited mucocutaneous syndrome [30]. Erythema multiforme major includes Stevens-Johnson syndrome and toxic epidermal necrolysis. These are severe blistering dermatoses characterized by mucocutaneous lesions, and differentiation between these disorders is based on the percentage of skin detachment. SJS is characterized by detachment of <10% of body surface area, and TEN is characterized by detachment of >30% of body surface area [31–33]. These disorders should be thought of as a systemic illness because of the extensive involvement of mucous membranes, and mortality rates as high as 50% for TEN have been reported [33]. The pathophysiology is not well understood but is likely mediated by drug-specific T cells.

Drug Reaction with Eosinophilia and Systemic Symptoms

The syndrome of drug reaction with eosinophilia and systemic symptoms is also called drug-induced hypersensitivity syndrome. It involves rash (typically erythematous and morbilliform, but presentations may vary), fever, eosinophilia, lymphadenopathy, and multiorgan dysfunction. Organs typically involved include the liver, kidneys, heart, and lungs, and while eosinophilia is common, it may not be present in up to 30% of cases. Onset is typically after 2–8 weeks but can be delayed up to 12 weeks from start of a medication [34, 35]. The pathogenesis is not well understood, but proposed mechanisms include abnormalities in drug detoxification enzymes with accumulation of reactive drug metabolites, reactivation of herpesviruses (EBV, CMV, HHV6, and HHV7), and genetic predisposition due to HLA alleles [34]. Unlike most other drug reactions, symptoms and organ involvement of DRESS may continue to progress for weeks after discontinuation of the drug and may persist for months after discontinuation [33]. Medications implicated include anticonvulsants (phenytoin), antibiotics (trimethoprim-sulfamethoxazole, minocycline, vancomycin), immunosuppressants (sulfasalazine, dapsone, cyclosporine), NSAIDs, D-penicillamine, hydrochlorothiazide, nevirapine,

and allopurinol [33]. Evidence that this syndrome has an immunologic basis includes the need for a sensitization period (reactions occur at least 7 days after the beginning of the drug therapy or after repeated exposure), no clear relationship to dose, the presence of blood and tissue eosinophilia, the presence of fever, positive rechallenges, and the presence of drug or drug-specific antibodies or drug-reactive T cells [36].

Vasculitis

Henoch-Schönlein purpura is predominantly a disease of children characterized by cutaneous vasculitis with the deposition of IgA. Although most often associated with an antecedent infection, particularly group A β -hemolytic streptococcus, it occasionally is associated with the recent intake of carbidopa/levodopa [33]. Henoch-Schönlein purpura also can present as a systemic vasculitis and can be seen in adults [37]. Drug-induced vasculitis can also be associated with hydralazine, antithyroid medications, minocycline, and penicillamine [33].

Hepatitis

Drug-induced liver injury most often is hepatotoxicity due to toxic effects of drugs (e.g., acetaminophen) but infrequently is hepatitis due to immunologic activation. Immunologic reactivity within the liver can manifest as cholestasis, hepatocellular damage, and granulomatous reactions. Although many drugs can cause allergic hepatitis, halothane and anticonvulsants (phenobarbital, carbamazepine, phenytoin) are most prominent [1].

Renal Failure

Drug-induced nephropathies include interstitial nephritis and membranous glomerulonephritis. Interstitial nephritis may result from high dose of β -lactam antibiotics or sulfonamides and is characterized by eosinophils in the urinary sediment (a positive Hansel stain) [33]. It may also be accompanied by fever, rash, peripheral eosinophilia, and high IgE [33]. Eosinophiluria is not always found in drug-induced renal damage, and gold, penicillamine, and allopurinol can induce a nephrotic syndrome, characterized by membranous glomerulonephritis [33, 38].

Hematologic Disorders

Immune-mediated hematologic disorders, such as thrombocytopenia and hemolytic anemia, are well described. Patients can present with thrombocytopenia, hemolytic anemia, or leukopenia. In most occurrences, drugs (e.g., penicillins) or their metabolic by-products bind to cellular membranes and initiate an immunologic reaction via the hapten mechanism by forming new antigenic determinants. IgG antibodies thus formed react with the blood elements, leading to sequestration by splenic macrophages. Cell lysis may occur if complement is activated. A less common mechanism has been documented with α -methyl dopa, levodopa, and procainamide, in which autoantibodies against red blood cells are formed, generating a clinical picture that looks like autoimmune hemolytic anemia [33].

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis can be seen with many drugs, including antimicrobial agents (nitrofurantoin, sulfonamides), anticonvulsants (phenytoin, carbamazepine), diuretics (hydrochlorothiazide), antiarrhythmics (amiodarone), narcotics (heroin, methadone, propoxyphene, cocaine), antirheumatics (gold, methotrexate, penicillamine, naproxen), and chemotherapeutics (bleomycin). The clinical picture is similar to that seen after inhalation of organic dusts from multiple sources, such as moldy hay (farmer's lung), bird proteins (pigeon breeder's disease), or contaminated humidifiers [39]. This syndrome is characterized by fever, nonproductive cough, and dyspnea associated with bilateral patchy infiltrates suggestive of a pulmonary infection.

Immunologic Reactions Due To Specific Agents

Antibiotics

Antibiotics are associated most commonly with immunologic drug reactions, probably due to their widespread and intermittent usage. Fatality from penicillin has been estimated to occur in 0.0001% of treatments, resulting in 400–800 deaths per

year during the 1970s [2]. Parenteral administration is associated with more allergic reactions, but it is unclear whether this is related to the route of administration or to the dose administered.

Penicillins and Other β -Lactams

Penicillins and other β -lactam antibiotics (cephalosporins, carbapenems, and monobactams) are small molecules, but they present a range of antigenic determinants to the immune system [40, 41]. Penicillins bind covalently to proteins by an amide linkage to the side chain ϵ -amino group on lysine residues, generating the “penicilloyl” residue (the major determinant), commercially available as penicilloyl polylysine and less well-characterized “minor” determinants, of which only penicillin G is commercially available [42]. Antibodies to the penicilloyl group constitute up to 95% of the responses to penicillin and penicillin allergy is not due to reactions to the β -lactam ring [17, 43]. Although up to 10% of the population may self-report allergy to penicillin, when evaluated with skin testing or other assays, the true incidence of penicillin allergy is <10% of those who self-report they are allergic, and rates may be as low as 0.3–3% (Grade II-2) [43]. IgE-mediated drug reactions require sufficient time for development of an antibody response, but allergic reactions can develop during the course of a single treatment or even manifest 2 weeks after termination of the treatment [18].

While IgE mediated, immediate hypersensitivity reactions to penicillin are the best studied, they can also cause delayed reactions, including serum sickness and delayed maculopapular eruptions. The delayed maculopapular or morbilliform rash commonly seen with ampicillin or amoxicillin in patients with infectious mononucleosis, other viral illnesses, chronic lymphocytic leukemia, or concomitant allopurinol therapy is not IgE mediated [1].

Cross-Reactivity of β -Lactams

Early studies with first-generation cephalosporins suggested strong but incomplete cross-reactivity with penicillin. However, more recent observations suggest that only about 2% of penicillin

skin test positive patients will react to cephalosporins. It is recommended that those with a reported history of penicillin allergy be skin tested prior to administration of a cephalosporin (Grade III); however, if penicillin-allergic patients are NOT skin tested, extrapolating from the approximation that, at most, only 10% of people with self-reported histories of penicillin allergy will have positive skin tests, the risk of reaction with cephalosporins is likely <1% (Grade III) [33]. Patients with a delayed, maculopapular (not urticarial) rash associated with intake of a penicillin (most often amoxicillin), especially in the context of a viral infection (Epstein-Barr virus or cytomegalovirus), are unlikely to have systemic reactions to penicillin or cephalosporins. Some guidelines recommend the use of cephalosporins without further evaluation in those with penicillin allergy by history who did not experience urticaria, angioedema, respiratory distress, or anaphylaxis (Grade III) [44].

About 25% of cephalosporin allergic patients will react to penicillin, and so penicillin skin testing is recommended prior to penicillin administration in those with cephalosporin allergy (Grade II-2) [45]. The major cross-reactivity between penicillin and cephalosporins is directed toward side chains, and not the β -lactam ring, and so for those with penicillin allergy, cephalosporins with similar side chains should be avoided (Grade III) [43]. For those allergic to ampicillin or amoxicillin, this includes cephalosporins with identical R1 side chains including cefaclor, cephalexin, cefprozil, cefadroxil, cefatrizine, cephaloglycin, and loracarbef, as well as those with similar R1 components, cefamandole and cefonicid [43]. Cephalosporin allergy does not cross all generations of the antibiotic class, and cross-reactivity is based on the similarity of R1 and/or R2 side chains (i.e., cefepime and ceftriaxone, cefoxitin and cephalothin) [43].

Carbapenems have very low cross-reactivity with penicillins. In one study only 1% of penicillin skin test positive patients were positive to imipenem, and all those with a negative skin test to imipenem passed challenges (Grade II-2) [46]. Aztreonam does not cross-react with any β -lactam antibiotics except for ceftazidime, due

to a common side chain, and penicillin- and cephalosporin-allergic patients may safely receive aztreonam, unless they specifically are allergic to ceftazidime (Grade III) [33]. There were no positive skin tests and no reactions to challenge with aztreonam in those with a history of penicillin allergy and positive penicillin skin testing (Grade II-2) [47].

Other Antibiotics

Reactions to sulfa drugs may be immunologically mediated and manifest as hives or anaphylaxis or both. The major concern for sulfa drugs is development of SJS/TEN, and it is crucial to consider these severe cutaneous adverse reactions in any patient with a rash in the context of sulfa drug administration. Vancomycin can cause mast cell degranulation directly, leading to the “red man syndrome.” The pseudoallergic activation of mast cells with vancomycin is functionally similar to the nonspecific degranulation of mast cells seen with radiocontrast material, although the red man syndrome is limited to the skin. It is unknown why this activation manifests as a diffuse erythema rather than hives and why is it limited to the skin.

Antiepileptics

Similar to other drugs, antiepileptic drugs can cause a maculopapular or morbilliform rash as well as severe cutaneous adverse reactions, including SJS/TEN and DRESS/DiHS [33, 48]. The concomitant administration of valproate and lamotrigine seems to increase the risk. Valproate is known to increase the half-life of lamotrigine, and the dose should be adjusted accordingly (Grade II-2) [49]. In some cases, these reactions clearly have an immunologic basis, with histocompatibility locus HLA-B*15:02 associated with severe cutaneous adverse reactions with both phenytoin and carbamazepine in Asian populations (Grade II-2) [50]. Genetic variants in hepatic enzyme CYP2C, including CYP2C9*3, have also been associated with severe cutaneous adverse reactions. These variants decrease clearance of plasma

phenytoin and higher levels of phenytoin were associated with development of these reactions (Grade II-2) [51].

Local Anesthetics

Bona fide reactions to local anesthetics are extremely rare, although there are many patients who profess that they have had reactions, mostly during dental procedures. The most generally accepted alternative explanations for these histories are that these either are vasovagal reactions or are due to the inadvertent intravenous injection of the local anesthetic agent with epinephrine. Some of these patients may be allergic to latex. A simple approach to these patients is to perform skin testing to reassure the patient and to switch to the alternate class of local anesthetic agent (benzoic acid esters versus amide-type local anesthetics) (Grade III) [2, 52].

General Anesthesia

The incidence of life-threatening immunologic reactions to drugs used in general anesthesia has been estimated to be 1 in 3500 to 1 in 6000 [53]. These reactions typically occur in the context of administration of multiple drugs. This situation obscures temporal relationships and complicates determination of the specific offending agent. The patient typically is unconscious and covered, delaying awareness that a systemic reaction is taking place. Increased ventilatory resistance or loss of blood pressure may be the earliest signs of anaphylaxis. Based on the demonstration of drug-specific IgE, 50% of these reactions may be IgE mediated, and the remainder are thought to be pseudoallergic. Muscle relaxants, such as suxamethonium, are the cause in approximately 60% of the IgE-mediated reactions. Quaternary ammonium ions, which are present in many drugs and cosmetics, may be the active epitope [54]. Other agents, such as hypnotics and morphine derivatives, occasionally are identified as causal. Some agents, such as tubocurarine, may be able to release

histamine from mast cells on a non-IgE-mediated basis, but the clinical importance of this is controversial [2, 53]. Latex sensitivity may also explain some episodes of intraoperative anaphylaxis [14].

Latex

Latex allergy is included in this chapter because sensitivity to latex proteins is an important consideration in patients presenting with immediate hypersensitivity reactions in the hospital. The early reports of anaphylaxis after exposure to latex were in patients undergoing barium enemas and in children with spina bifida. In the 1990s, it became apparent that many individuals were sensitized to latex, and individuals at highest risk are patients who have undergone multiple surgeries or invasive procedures, health-care professionals, and latex workers. Prevalence of anti-latex IgE in health-care workers is 9–18% compared with about 6% in unselected blood donors [55]. This higher rate of sensitization has been attributed to the institution of universal precautions in 1987 with the concomitant increased use of poorly manufactured rubber gloves coated with cornstarch [56]. Although many patients present with dermatitis, conjunctivitis, rhinitis, or asthma, life-threatening allergic reactions can be the initial presentation for latex allergy. Powdered gloves are the most allergenic because the powder acts as a vehicle for the latex proteins. Procedures performed on latex-sensitive persons are conducted in a latex-free environment. Latex is a natural product manufactured from the sap of the rubber tree and contains many proteins, several of which are allergenic in susceptible individuals. An important corollary is that fruit of other plants, particularly those of tropical origin, such as kiwi, banana, and avocado, contains similar proteins and can be cross-reactive. Cross-reactivity between latex and chestnuts, grass pollen, and ragweed pollen also has been reported. Seasonal rhinitis and food allergies are often present in latex-sensitive patients, and inadvertent exposure to specific foods can cause anaphylactic reactions [56].

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs can activate the immune system in both an IgE-dependent and an IgE-independent fashion. Typically IgE-dependent reactions to NSAIDs are to a specific drug, while the IgE-independent, or pseudoallergic, reactions are typically to all NSAIDs as a class. Urticarial and anaphylactic reactions to aspirin and NSAIDs tend to occur within minutes of oral ingestion [57]. Clinical manifestations of pseudoallergic reactions include bronchospasm and exacerbations of rhinosinusitis and occasionally urticaria or angioedema. Vascular collapse is not typically part of this picture, but bronchospasm can be profound [57]. Aspirin-induced bronchospasm occurs in 30–40% of asthmatics who have concomitant nasal polyps. The clinical syndrome of aspirin-exacerbated respiratory disease, or triad asthma, refers to patients with asthma, sinusitis with nasal polyposis, and sensitivity to aspirin and other NSAIDs. These reactions to NSAIDs manifest by upper and/or lower respiratory symptoms and can include rhinorrhea, conjunctivitis, periorbital edema, laryngospasm, and prolonged bronchospasm [57]. Since the type of reaction is typically to NSAIDs as a class, it suggests a central role for COX-1 inhibition, and although specifics of the pathophysiology are unknown, it seems to involve activation of macrophages, mast cells, and endothelial cells, leading to excessive production of vasoactive lipid-derived molecules (e.g., leukotrienes and prostaglandins) [57]. Increased production of leukotriene E₄, the terminal metabolic product of cystinyl leukotriene production, has been shown in the urine of these patients. Increased levels of a key enzyme, leukotriene synthase, have been shown in lung tissue from some of these patients. This finding suggests that when the cyclooxygenase pathway is inhibited, these patients may overproduce proinflammatory leukotrienes [58].

Radiographic Contrast Material

Reactions to radiographic contrast material have been discussed previously as the best example of a

non-IgE-mediated anaphylactic drug reaction. The most important approach to these reactions is to be prepared for them, to identify patients who have had previous reactions, and to premedicate or use low-ionic-strength contrast material in susceptible patients. One must be prepared because even without a history of previous reactions, 1–2% of patients have a systemic reaction, which can include cutaneous hives, angioedema, wheezing, and anaphylaxis. Severe reactions were rare in a large-scale Japanese study, occurring in 0.04–0.22% of the reactions and resulted in 1 death per 169,000 procedures [59]. History of a previous reaction to radiocontrast material is the best historical clue to predict a reaction. Of patients with a generalized reaction to a previous exposure, 17–35% react on a subsequent exposure at an increased risk of 8–35 times that of patients without a prior reaction [60]. Other less important risk factors that have been recognized include a history of asthma, a history of skin test positivity to common allergens, and a history of allergy to penicillin [59]. Factors that are NOT predictive of a reaction include a history of allergic reactions to seafood, history of cutaneous reactivity to iodine-containing skin disinfectants, parotid swelling after radiocontrast material administration, and a positive cutaneous reaction to radiocontrast material [1].

Pretreatment with diphenhydramine and prednisone (Table 4) reduces the frequency of repeat reactions to approximately 10% and reduces their severity. The combination of premedication and the use of low osmolar radiocontrast material in patients with a history of severe reactivity reduces the risk of systemic reaction to approximately 0.7% (Grade III) [61]. The use of β -blockers

Table 4 Management of patients at risk for reactions to radiographic contrast media

- | |
|--|
| 1. Remove any β -blockers if possible |
| 2. Have emergency therapy available |
| 3. Pretreat with prednisone 50 mg PO 13, 7, and 1 h prior to the procedure and diphenhydramine 50 mg IM or PO 1 h prior to the procedure |
| 4. For patients with a history of generalized anaphylaxis, pretreat and use a lower osmolar radiographic contrast medium |

interferes with the action of epinephrine and complicates resuscitation of patients from anaphylaxis. These agents should be stopped, if clinically possible, before radiocontrast material is administered. Table 4 lists recommendations for administration of radiocontrast material in susceptible patients [59].

Biologics

As mentioned at the beginning of the chapter, horse serum was used extensively in the first half of the twentieth century to treat a variety of infectious diseases and was associated with frequent immunologic reactions. More recently, purified polyclonal IgG, purified Fab fragments of polyclonal IgG, monoclonal IgG, and humanized monoclonal IgG have provided safer, biologically derived therapeutic agents. An example of a therapeutic material containing unfractionated horse globulins (not purified IgG) is black widow spider antivenin [62]. An example of a material containing predominantly polyclonal horse IgG currently in use is antithymocyte globulin [62]. Crotalidae polyvalent immune Fab and digoxin immune Fab antibody (sheep IgG) are produced from sheep by papain digestion of serum from immunized sheep and the subsequent isolation of the less immunogenic Fab portion of the antibody [28]. This preparation has replaced polyclonal horse IgG antivenin (Crotalidae) polyvalent for the treatment of crotaline snake bites.

Antithymocyte globulin is an effective treatment for severe, resistant aplastic anemia. Because this is purified equine IgG, there is ample opportunity for immune activation even in patients who have severely dysfunctional bone marrow and are leukopenic. In a prospective study of 35 patients treated for aplastic anemia, 86% developed serum sickness. Urticaria and anaphylaxis were rare, but one patient died [63, 64]. In a study of 43 patients receiving multiple courses of treatment, serum sickness occurred in 66% of the patients [65].

Antivenin Crotalidae polyvalent also has been associated with numerous case reports of acute allergic reactions and a reported incidence rate

ranging from 23% to 56% [28]. In a prospective study, the incidence of acute reactions to the potentially less immunogenic Crotalidae polyvalent immune Fab was 14%, and most of the events were of mild to moderate severity. Crotalidae polyvalent immune Fab has not been used as extensively as antivenin (Crotalidae) polyvalent, however, and these differences should be considered preliminary. Serum sickness also is seen with each of these agents, with reported rates between 15% and 86% of patients receiving antivenin Crotalidae polyvalent and 16% of patients receiving Crotalidae polyvalent immune Fab [28].

A postmarketing survey of the efficacy and safety of digoxin immune Fab included 717 patients with life-threatening digitalis intoxication treated in 487 hospitals. Six subjects had adverse reactions that probably or possibly were due to the Fab fragments. These reactions included pruritic rashes, angioedema, chills, and thrombocytopenia and occurred more frequently in patients with a history of allergic reactions. None of the reactions were life-threatening, and all resolved with cessation of the infusion and appropriate medical treatment [66].

Monoclonal antibodies have been useful clinically, although the first ones developed were murine monoclonal antibodies, which were associated with anaphylaxis in some patients [33]. To decrease the immune response against the murine monoclonal antibodies, chimeric and humanized monoclonal antibodies were engineered. Chimeric monoclonal antibodies are composed of murine variable regions fused onto human constant region, and humanized monoclonal antibodies are composed almost entirely of human antibodies, except for the hypervariable regions necessary to retain immunologic activity and bind antigen. Examples of chimeric monoclonal antibodies include infliximab (Remicade[®], antitumor necrosis factor- α) and rituximab (Rituxan[®], anti-CD20). Infusion reactions to the first infusion of rituximab including flushing, rash, and shortness of breath are common, and the mechanism is not well understood, although it is not thought to be IgE mediated [67]. One chimeric monoclonal antibody, cetuximab (Erbix[®], anti-epidermal

growth factor receptor), caused anaphylaxis with a geographical variation in the United States, with national rates of 6% or less but rates of over 20% in the southeastern United States [68]. The basis for this was determined to be an IgE-mediated anaphylaxis, with IgE directed against a specific carbohydrate, galactose- α -1,3-galactose (α -gal), on the Fab portion of the antibody [68]. This IgE directed against α -gal was present in serum even prior to the administration of cetuximab, and it was later determined that IgE specific for α -gal may have developed due to prior tick bites from the tick *Amblyomma americanum*, which has a geographic distribution that overlaps with areas of increased anaphylaxis to cetuximab [68, 69].

An example of a humanized monoclonal antibody is omalizumab (Xolair[®], anti-IgE), which is >95% human antibody. Despite this, there have been rare reports of anaphylaxis with omalizumab (0.09%) with some anaphylactic episodes that were delayed over 2 h after injection of omalizumab [70]. There have been reports of other types of immunologic reactions with other humanized monoclonal antibodies, including serum sickness with natalizumab (Tysabri[®], anti- α -4 subunit of integrin molecules).

Another approach has been to engineer novel proteins consisting of sequences for soluble human receptors and the Fc region of human IgG. The Fc region of IgG imparts a long half-life to these agents. An example is etanercept (US trade name Enbrel[®]), a fusion protein containing the extracellular ligand-binding portion of the human tumor necrosis factor receptor linked to the Fc portion of human IgG₁ [62]. Immune-mediated reactions to etanercept have been described and can include urticaria and vasculitis [33]. Finally, there are fully human monoclonal antibodies, produced in transgenic mice or via phage display library in bacteria, which allows for production of antibody without nonhuman components [71]. An example of human monoclonal antibody adalimumab (US trade name Humira[®], anti-TNF), which despite the fact that it is fully human, has still been associated with immediate infusion reactions

similar to etanercept and infliximab, which are not likely IgE mediated [72].

Differential Diagnosis

In a hospitalized patient who has had a severe systemic reaction, the main considerations are allergic reactions to drugs, blood products, foods, or latex, distinguishing these anaphylactic reactions from shock. Cutaneous eruptions, such as hives (with or without angioedema) or angioedema, are typical manifestations of an acute allergic reaction. In the acute setting, the presence of hives is the best predictor that a reaction is allergic although the absence of hives is not helpful [73].

Angioedema (with or without hives, localized or diffuse) may be due to an allergic reaction or to a known pharmacologic activity of a drug in a sensitive patient (NSAIDs or angiotensin-converting enzyme inhibitors). Other causes of angioedema need to be considered, however, including hereditary angioedema and acquired angioedema. These latter diseases are caused by deficiencies in the quantity or function of a protein called *C1 esterase inhibitor* and should not be accompanied by urticaria. C1 esterase inhibitor exerts regulatory control on complement activation and activation of vasoactive peptides called *kinins*.

Severe cutaneous eruptions may be due to drugs, infections, or intercurrent disease. Infections associated with severe dermatitis include upper respiratory viruses, cytomegalovirus, human immunodeficiency virus, Epstein-Barr virus, viral hepatitis, staphylococcal scalded skin syndrome, and *Staphylococcus aureus*-induced toxic shock syndrome. Concomitant collagen vascular diseases, lymphoma, porphyria, and syphilis also can be the cause of severe cutaneous eruptions (Table 5) [19, 48].

Crucial diagnostic concerns are distinguishing anaphylaxis from shock from other causes and recognizing pseudoallergic reactions when they occur. The possibility of a pseudoallergic reaction should be considered if a patient becomes symptomatic in the context of

administration of an agent known to cause this type of a reaction.

When one has determined that a specific reaction is an allergic or a pseudoallergic reaction, the work to determine the cause of the reaction begins. A decision regarding which of many suspects is the etiologic agent is not straightforward and often cannot be determined absolutely. As in all aspects of medicine, a detailed history is the beginning step. The history as it relates to a possible drug allergy must include a detailed analysis of all medications that have been used, including prescribed medications, over-the-counter medications, dietary supplements, and herbals. If the

reactions occurred in the operating room, exposure to latex may be important. In the emergency department, inadvertent exposure to foods in a patient with food allergy is a possible cause of a systemic reaction. The temporal relationship between administration of a suspected agent and the onset of the reaction is crucial. A history of a previous reaction to a suspected or chemically similar drug is useful, whereas a history of other allergies or a family history of a reaction to a given drug is not useful. For reactions with later onset, such as maculopapular rashes, other rashes, or serum sickness, temporal relationships may be much less clear.

The physical examination is useful because some manifestations are more typically “allergic” than others. In the acute setting, a patient with rapid onset of vascular collapse often can be recognized easily to be having an anaphylactic reaction because of associated urticaria. Other cutaneous presentations, such as maculopapular rashes, diffuse erythema, or the symptom of pruritus, are less specific, however, and there may be no cutaneous changes at all. Wheezing can be a prominent sign of anaphylaxis, although in the operating room, this may be manifest only as increased resistance to ventilation. Fever typically is not part of an acute allergic reaction (but it can be a manifestation of more delayed reactions, such as a drug fever or serum sickness), and its presence should raise the likelihood of sepsis.

Testing

In Vitro Tests

Results from general laboratory testing can be helpful. Elevated numbers of eosinophils generally indicate an allergic process. Antigen-specific IgE measurements are helpful if positive but have poor negative predictive value. Products from mast cells can be measured. Plasma levels of histamine increase rapidly (approximately 5–10 min) after an allergic reaction and return to baseline within 30 min. Plasma samples must be handled carefully and processed promptly. Determination of urinary *N*-methylhistamine in a 24-h collection beginning immediately after the onset

of a reaction can be helpful if the values are quite elevated. Levels of β -tryptase increase more slowly than serum histamine (peak at about 1 h) and stay elevated longer (3–4 h) [14]. These laboratory tests are complementary, but normal values do not rule out an allergic reaction. There is no value in ordering a total IgE level.

The syndromes of hereditary angioedema and acquired angioedema are due to abnormal complement pathway activation and need to be considered in patients with angioedema without urticaria. Typically, these syndromes have low levels of C4 between attacks and nearly absent C4 during attacks. The C4 level may help to differentiate these conditions from other causes of angioedema; however, by itself a low C4 is not diagnostic of hereditary angioedema. Complement activation occurs in a variety of conditions seen in the hospital, and the most appropriate diagnostic test for hereditary angioedema is to measure level and function of C1 esterase inhibitor.

In Vivo Tests

Skin tests can be useful diagnostic tools to distinguish among various possible etiologic agents that may have precipitated an allergic reaction; however, they have many limitations. One limitation is that for many drugs, the reactive species may be a metabolic product or a haptenated protein and not the original drug itself. The best-characterized skin tests are those for penicillins, but they are suboptimal because the minor determinant mix is not commercially available.

To perform skin prick tests, one first must determine if the patient can react appropriately to skin tests by placing a positive (histamine) and negative (saline) control. The main cause of lack of reactivity to the positive control is recent administration of an antihistamine, but conditions such as uremia also give a false-negative reaction to histamine. The most common cause of unexpected reactivity to the negative control is inappropriate activation of dermal mast cells by the physical stimulus of pricking the skin. This activation occurs in patients who have dermatographism. One cannot interpret skin tests in patients when the positive control is negative or the negative control is positive. For penicillin testing, it first should be established that

the patient can mount a skin response to histamine that is substantially (>3 mm wheal with erythema) more than the saline control. Then skin tests should be performed to the drug in question. Skin tests for other drugs are useful if positive, but if negative they do not exclude the possibility of an allergy to the tested drug, and the gold standard is to perform a challenge to the drug after negative skin testing. Tests for IgE-mediated processes have no predictive value for non-IgE-mediated immunologic reactions, including serum sickness, and dermatologic reactions, including morbilliform rashes and severe cutaneous adverse reactions.

Treatment

Anaphylaxis

Treatment of anaphylaxis requires the immediate intramuscular administration of epinephrine, in the mid-anterolateral thigh to maximize absorption. Typically the dose is 0.3 mg of a 1:1000 (1 mg/mL) solution, and epinephrine may be readministered 5–15 min later if needed. Another important measure is ensuring the patient is supine and not sitting or standing (Grade II-2) [19]. Intravenous access should be established with large-bore intravenous catheter(s) for infusion of intravenous fluids if needed, and high-flow supplemental oxygen should be given [19, 24]. Vital signs should be monitored regularly, and, if needed at any time, cardiopulmonary resuscitation according to current advanced cardiac life-support guidelines should be followed (Fig. 3). Adjunctive treatments include antihistamines and corticosteroids, which may be useful but should not be used instead of epinephrine (Grade III). Diphenhydramine (US trade name Benadryl[®]), 0.5 to 1 mg/kg up to 50 mg intravenously or intramuscularly, and methylprednisolone (US trade name Solu-Medrol[®]), 1 mg/kg intravenously, may also be given. Other treatments that may be helpful include nebulized albuterol for bronchospasm, as well as racemic epinephrine via nebulizer, especially in the cases for treatment of laryngeal edema or severe bronchospasm. The ameliorative effect of epinephrine

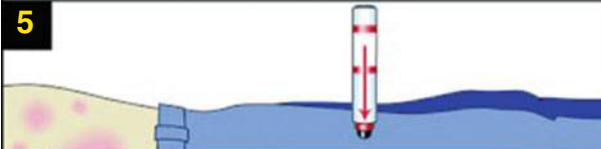

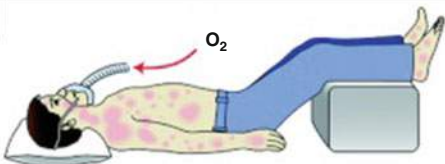

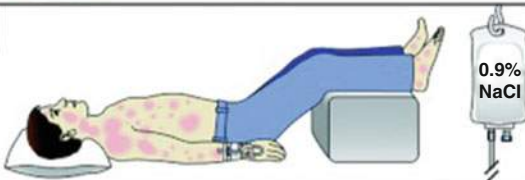

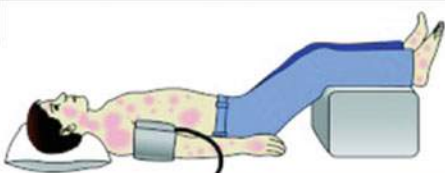

1	Have a written emergency protocol for recognition and treatment of anaphylaxis and rehearse it regularly.
2	Remove exposure to the trigger if possible, eg. discontinue an intravenous diagnostic or therapeutic agent that seems to be triggering symptoms.
3	 <p>Assess the patient's circulation, airway, breathing, mental status, skin, and body weight (mass).</p>
4	 <p>Promptly and simultaneously, perform steps 4, 5 and 6.</p>
5	 <p>Inject epinephrine (adrenaline) intramuscularly in the mid-anterolateral aspect of the thigh, 0.01 mg/kg of a 1:1,000 (1 mg/mL) solution, maximum of 0.5 mg (adult) or 0.3 mg (child); record the time of the dose and repeat it in 5–15 minutes, if needed. Most patients respond to 1 or 2 doses.</p>
6	 <p>Place patient on the back or in a position of comfort if there is respiratory distress and/or vomiting; elevate the lower extremities; fatality can occur within seconds if patient stands or sits suddenly.</p>
7	 <p>When indicated, give high-flow supplemental oxygen (6–8 L/minute), by face mask or oropharyngeal airway.</p>
8	 <p>Establish intravenous access using needles or catheters with wide-bore cannulae (14–16 gauge). When indicated, give 1–2 litres of 0.9% (isotonic) saline rapidly (e.g. 5–10 mL/kg in the first 5–10 minutes to an adult; 10 mL/kg to a child).</p>
9	 <p>When indicated at any time, perform cardiopulmonary resuscitation with continuous chest compressions.</p>
10	 <p>In addition,</p> <p>At frequent, regular intervals, monitor patient's blood pressure, cardiac rate and function, respiratory status, and oxygenation (monitor continuously, if possible).</p>

Fig. 3 Treatment of anaphylaxis (From Ref. [19])

in anaphylaxis is mediated predominantly through β_2 -receptors, and the concurrent treatment of a patient with nonselective and selective β -blockers can interfere with its effect. Patients who have anaphylaxis while on a β -blocker are notoriously difficult to treat. In this setting, glucagon is given, 1 to 5 mg intravenously as a bolus followed by an infusion of 5–15 $\mu\text{g}/\text{min}$ titrated to the clinical response (Grade III) [14]. The effects of epinephrine may give a false sense of security; close monitoring and support are necessary after the initiation of a reaction since protracted and biphasic patterns of anaphylaxis occur.

Angioedema

Compromise of the airway constitutes a medical emergency. A patient with angioedema due to either an allergic reaction or lack of C1 esterase inhibitor activity may experience closure of the larynx. Intubation in this situation is difficult and may be unsuccessful, and the local trauma of an unsuccessful intubation may make angioedema worse. In this situation, it is essential to act as soon as the problem is recognized and to be ready to perform an emergency cricothyrotomy. Specific treatments that target the pathway of bradykinin-mediated angioedema have been developed and are useful in treatment of hereditary and ACE-inhibitor-induced angioedema. Treatment with the bradykinin B2 receptor antagonist icatibant (US trade name Firazyr[®]) significantly shortens the time for improvement in those with ACE-inhibitor angioedema from 11.7 h to 2.0 h, when compared with steroid and antihistamine treatment. Icatibant also reduced the median time to complete symptom resolution from 27.1 h to 8.0 h (Grade I) [74].

Severe Cutaneous Adverse Reactions

The most important treatment for severe cutaneous adverse reactions is identification and removal of the offending agent. Supportive care including transfer to a burn unit in the case of TEN may be necessary. Corticosteroid use in SJS is controversial and is contraindicated in TEN.

Intravenous immune globulin, or IVIG (dosed at 0.5 g to 1 g/kg/day for 3–4 days), has been studied for treatment of TEN, and results have been mixed, without clear evidence of benefit (Grade III) [33, 75]. Anti-TNF agents have some limited evidence of potential benefit in treatment of TEN (Grade III) [33]. For DRESS/DiHS, if there is not severe organ involvement, management with supportive care and topical steroids alone may be adequate (Grade II-2) [76]. If there is evidence of severe organ involvement, administration of prednisone 0.5 mg to 2.0 mg/kg/day has been used (Grade III). Once clinical improvement occurs, a very gradual tapering of steroids may help reduce the risk of rebound symptoms (Grade III) [77].

Readministration of the Drug via Desensitization

Avoidance of the offending agent is the simplest approach, but there are clinical settings in which administration of the offending drug is clearly indicated. An example is treatment of a pregnant woman who is allergic to penicillin and has syphilis. In this case, there is no acceptable alternative and desensitization is necessary.

Desensitization is a potentially life-threatening procedure that should be performed only by physicians with substantial experience, such as allergy/immunology specialists, and should be done in carefully controlled settings. The most extensive experience in desensitization to drugs is with β -lactam antibiotics, although this approach has been generalized to include many other agents. In general, patients with acute systemic reactions (urticaria or anaphylaxis) are good candidates for desensitization because there is good reason to think that their reactions are mediated by IgE. Patients with positive skin tests to the suspect drug are likely at greater risk than patients with negative skin tests. The presence of a negative skin test is not a guarantee, however, that the patient can tolerate the drug.

To perform desensitizations, the patient is placed in a setting that allows careful monitoring. After informed consent is obtained, an initial dose

of the drug that is approximately 10,000-fold less than the therapeutic dose is administered, and the patient is observed for a period of time. Incremental doses are administered until the therapeutic dose is achieved. Desensitization is maintained only as long as the drug is administered on a frequent basis. Patients with atypical reactions (e.g., morbilliform rashes) to agents known to cause IgE-mediated reactions and negative skin tests often are not desensitized but rather are given test doses (1/10 of a full dose) in a controlled setting because the index of suspicion of an IgE-mediated allergic reaction is not high. Drugs which caused severe cutaneous adverse reactions are not good candidates for desensitization. Examples of agents for which desensitization is not used are antiepileptic drugs in patients who have had severe cutaneous reactions. There is a strong relative contraindication to desensitizing patients to sulfa drugs especially in patients who are not immunosuppressed. Although the cutaneous reactions to sulfa drugs may either be T-cell mediated or not immune mediated, patients who are immunosuppressed may have successful desensitization to sulfa drugs. Trimethoprim-sulfamethoxazole has been administered successfully (using a desensitization protocol) to patients with human immunodeficiency virus and to patients who are status post-lung transplantation (Grade III) [78, 79].

The use of mind-altering substances predates written history. As a consequence, so do the withdrawal syndromes associated with the abrupt cessation of these substances. The discussion of withdrawal requires defining the following terms: *narcotic*, *tolerance*, *dependence*, *addiction*, *withdrawal*, and *cross-tolerance*. Defining these words not only allows for better understanding but also enables the appropriate application of these terms (Fig. 1). *Narcotic* literally means any drug that induces sleep, although it also has the socio-legal implication of an illegal substance. For the purpose of maintaining clarity, drugs should be referred to by their clinical class (i.e., opioids, sedative-hypnotics, and stimulants [e.g., cocaine and amphetamines]). *Tolerance* is the process by which increasing drug dosages are required to obtain a desired effect and can be represented graphically by a shift in the dose-response curve to the right. This effect is exemplified by heroin tolerance, in which a tolerant person's routine dose would be lethal to a naïve user. Tolerance can be mediated via receptor modulation (opioids), induced metabolism (barbiturates), or both (ethanol). *Dependence* implies that cessation of the drug leads to withdrawal symptoms. *Withdrawal* can be physical (i.e., autonomic instability, nausea, vomiting, diarrhea, hyperactivity, or altered mentation), psychological (i.e., emotional symptoms and craving), or both. Withdrawal is a response to lowered drug concentrations resulting in a predictable constellation of symptoms (e.g., tremor,

Fig. 1 Schematic representation of receptor activity

hypertension, nausea, vomiting, and diarrhea). These symptoms are reversible if the drug in question is reintroduced. Not all withdrawal symptoms are negative or unpleasant. Piloerection, yawning, and lacrimation are associated with opioid withdrawal, but most patients do not perceive these symptoms as negative compared with their drug craving, nausea, and vomiting. When continued use of a drug induces socially unacceptable behavior (theft) or results in unacceptable outcomes (a driving-while-intoxicated conviction), the user of the drug is considered *addicted*.

Understanding *cross-tolerance* is the key to treating most withdrawal syndromes. The concept is that two different drugs share enough common receptor or metabolic activity such that one drug can be substituted for the other to prevent or treat withdrawal. This principle is most important for treatment of withdrawal from heroin/other opiates/opioids, alcohol, benzodiazepines, barbiturates, baclofen, and more recently γ -hydroxybutyrate (GHB) or its analogues γ -butyrolactone (GBL) and 1,4-butanediol.

The nature of withdrawal and self-treatment behavior makes it impossible to describe its actual incidence. It would be expected that most dependent users go through mild withdrawal every day. The alcoholic who awakens in the morning and

drinks an “eye-opener” may best exemplify this concept. Current estimates state that almost 17 million adult Americans are alcoholics, with a 2:1 male-to-female ratio [1]. It is estimated that 2,000,000 Americans are either opioid dependent or opioid abusers, only 15% of whom are in methadone maintenance programs [2]. More recently, GHB and GBL abuse and dependence have been described, but this remains unquantified. Benzodiazepines are some of the most commonly prescribed drugs worldwide. Tolerance to any of these drugs can lead to withdrawal, and in the case of alcohol and the sedative-hypnotics (including GHB/GBL), withdrawal can be life-threatening.

History

Spanish physicians described symptoms consistent with delirium tremens (DTs) in the first half of the nineteenth century [3]. Seven clinical cases were reported in the 1840s and were referred to as *alcoholic chorea* or *ataxis fever*. These patients received various treatments ranging from bleeding with leeches to tincture of opium. The differential diagnosis at that time included epilepsy and meningitis.

In North America, Osler [4] reportedly recognized DTs as a complication of alcoholism in the early part of the twentieth century. His recommended treatment consisted of chloral hydrate, potassium bromide, hyoscine, opium, cessation of alcohol, and bed rest. Around 1919, Victor and Adams [5] credited Mellanby as being “among the first to become cognizant of the immediate adjustments of the nervous system to alcoholic intoxication.” Alterations to Osler’s treatment included the addition of restraints, paraldehyde, and strychnine or ergots to control tremor. Despite these innovations, mortality remained around 14%. It was not until the early 1950s with the work of Victor and Adams [5] and Isbell and colleagues [6] that DTs was uniformly accepted as a manifestation of alcohol abstinence. At the same time, treatment regimens began to focus on rehydration, substrate supplementation, and supportive care. By the early 1960s, mortality

approached 5.4% at Philadelphia General Hospital [7]. Studies in the 1960s comparing paraldehyde and antipsychotics showed a 35% mortality rate with promazine versus a 4.5% mortality rate with paraldehyde [8]. In 1975, benzodiazepines were compared with paraldehyde, and a demonstrable benefit was recognized for this new class of drug in the treatment of alcohol withdrawal. Since 1976, the mortality of alcohol withdrawal has been expected to approach zero, unless insufficient therapy is provided [9]. Mortality still results from common medical conditions that force alcohol abstinence. Pancreatitis, pneumonia, head trauma, and peptic ulcers commonly precede alcohol withdrawal [10]. A delay in diagnosis and treatment of these entities because of a focus on the highly visible manifestations of withdrawal can result in significant morbidity and mortality.

Mind-altering agents can occur naturally and can also be synthesized. As new agents are developed, the potential for abuse, dependency, and withdrawal exists. GHB use has increased since the 1980s [2]. Meanwhile, the use of cocaine in the United States has declined from its peak of 5.7 million users in 1985 to 1.7 million in 2012 [2]. By contrast, heroin use has been on the rise. Based on the 2012 US National Survey on Drug Use and Health, 467,000 Americans are addicted to heroin. In addition, the survey estimated that there are 2.1 million Americans with substance use disorders related to prescription opioids. Globally, it is estimated that there are 27 million people that use drugs on a regular basis (dependence), of which 12.7 million use the injectable route for administration [11]. International opioid use has also grown significantly, especially in Eastern and Southeastern Europe, South Asia, and Oceania [11]. A basic understanding of the pathophysiology of withdrawal and its treatment has general applicability to any withdrawal syndrome, new or well known.

Pathophysiology

Withdrawal is a phenomenon of altered neurochemistry with the central nervous system (CNS) as the most consequential target. Under normal

conditions, the CNS maintains a balance between excitation and inhibition. Although there are several ways to achieve this balance, excitation is usually constant, and actions occur through removal of inhibitory tone [11–13]. Two major neurotransmitters in the CNS are glutamate and γ -aminobutyric acid (GABA). Glutamate's effects at the *N*-methyl-D-aspartate (NMDA) receptors increase intracellular calcium, resulting in excitation [14]. Stimulation of GABA-A receptors increases inhibitory tone via chloride (Cl^-) channel opening. This Cl^- channel is surrounded by receptors, which when activated exert various effects on the channel. In the presence of GABA, stimulation of the benzodiazepine receptor increases the frequency of Cl^- channel opening, depolarizing, and thus inhibiting the cell (Fig. 2) [15]. The barbiturate receptor increases the duration of Cl^- channel opening, resulting in a similar effect [15]. Although this action is facilitated by the presence of GABA, the anesthetic barbiturates can depolarize the cell even in the relative absence of GABA. GHB appears to exert its effect via the GABA-B receptor, but there is evidence of a G protein-mediated GHB receptor as well [16]. Although it previously was unclear how certain agents (alcohol, propofol, and inhaled anesthetics) interacted with the GABA-A receptor, there is now mounting evidence that these drugs work via binding specific amino acid residues on ligand-gated ion channels to enhance receptor function [17, 18]. Most notable, chronic alcoholism causes a shift in GABA-A receptor subunits such that the α_1 subunit is under-expressed and the α_4 and γ_1 subunits are over-expressed [19]. This conformational change defines dependence and cross-tolerance to benzodiazepines [19].

The most studied excitatory receptor in the CNS is the NMDA receptor. This receptor controls a voltage-gated and ligand-dependent Ca^{2+} channel. Calcium and sodium influx result in cell depolarization, causing CNS stimulation. Many drugs act as NMDA receptor antagonists, including ethanol, ketamine, phencyclidine, and dextrophan, the metabolite of dextromethorphan [20–23].

Finally, opioids stimulate the opioid receptor subtypes μ , κ , and δ to varying extents. Although

Fig. 2 Idealized model of γ -aminobutyric acid (GABA)-benzodiazepine (BZ)-chloride (Cl^-) channel at axosomatic (postsynaptic) inhibitory synapses. (a) Presynaptic and postsynaptic elements; *ap* action potential, *Gad* glutamic acid decarboxylase, *EC* extracellular, *IC* intracellular, *ipsp* inhibitory postsynaptic potential. (b) GABA-BZ receptor interactions influencing permeability of chloride channels. Neutral: GABA receptor binds GABA (G) with moderate affinity in the absence of BZ ligand. BZ agonist:

direct BZ agonist (B) enhances GABA affinity for its receptor, resulting in maximal chloride permeability. Inverse agonist: inverse agonists bound to BZ receptor result in poor GABA affinity and markedly reduced chloride permeability (From Rech RH: *Drugs to treat anxieties and related disorders*. In Brody TM, Larner J, Minneman KP: *Human Pharmacology: Molecular to Clinical*, 3rd ed. St. Louis, Mosby, 1998, p 367, with permission)

there are many different opioids available, the common pathway for the development of dependence is stimulation of the μ receptor. Stimulation of opioid receptors by opioids begins a cascade of events, mediated via G proteins, that alter the cell's conductance and decrease intracellular adenylyl cyclase [24]. Outward potassium channels are activated, decreasing intracellular potassium, hyperpolarizing the cell, and inhibiting its activation [25, 26]. The decrease in adenylyl cyclase results in less cyclic adenosine monophosphate (cAMP), preventing protein kinase-mediated activation of Ca^{2+} influx

(Fig. 3) [27]. The net result is to hyperpolarize the cell and prevent neurotransmission of glutamate and substance P, which manifests clinically as CNS depression and analgesia.

Chronic receptor alteration by a drug results in changes in the receptors such that a constant concentration of that drug is needed to maintain normal baseline neuronal activity. When the drug is stopped abruptly, or as the serum concentration drops below threshold, the patient manifests withdrawal symptoms specific to the class of drug used. For sedatives, the result is noradrenergic hyperactivity in the locus caeruleus. This

hyperactivity may be produced by enhanced NMDA activity or decreased GABA-A tone. CNS excitation is the end result and leads to altered mental status, hyperactive muscular activity with resultant hyperthermia, and rhabdomyolysis [28].

Chronic opioid use leads to cellular and synaptic adaptations. These adaptations include

desensitization and internalization, or down-regulation, of receptors (removal of surface receptors), leading to tolerance [29, 30]. In addition to these processes, counteradaptation occurs. Activation of the nuclear transcription factor CREB (cAMP-responsive element-binding protein) increases the expression of adenylyl cyclase in the locus caeruleus, which may explain the autonomic hyperactivity that occurs in opioid withdrawal [31]. These compensatory changes also are a form of tolerance, increasing cellular excitability and requiring the presence of the drug to maintain basal activity. The best-studied adaptation is the CREB-mediated increase in adenylyl cyclase, which results in Ca^{2+} influx and cellular depolarization. In this excitable state, the user experiences withdrawal when opioid use is discontinued or when an opioid antagonist, such as naloxone, is administered.

Fig. 3 Mechanism of action of opioids on neurons. Opioid receptors μ , δ , and κ are coupled negatively to adenylyl cyclase by G proteins (G_i). Activation of an opioid receptor by an agonist decreases activity of adenylyl cyclase, resulting in a decrease in the production of cyclic adenosine monophosphate (*cAMP*). This leads to an increase in the efflux of K^+ (primarily with μ and δ opioid receptors), cellular hyperpolarization, a decrease in the influx of Ca^{2+} (primarily with κ opioid receptors), and lower intracellular concentrations of free calcium. The overall consequence is a decrease in the neuronal release of neurotransmitters. Opioid receptors also may be coupled by G proteins to intracellular second messengers other than cAMP (From Brody TM, Larner J, Minneman KP: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, with permission)

Toxic Effects: Withdrawal Syndrome

Although there is a great deal of overlap between different substances and their associated withdrawal syndromes, several drugs are discussed individually. These syndromes are alcohol, sedative-hypnotics (including GHB/GBL), opioids, and cocaine (Table 1). Finally, the unique aspects of neonatal withdrawal syndromes are discussed.

Alcohol Withdrawal

Alcohol withdrawal is one of the most common withdrawal syndromes, after those of nicotine and caffeine. The alcohol withdrawal syndrome is multifaceted and should be considered a spectrum. The discrete aspects of alcohol withdrawal

Table 1 Vital signs and mental status changes in withdrawal

	Opioids	Sedative-hypnotics ^a	Alcohol	Cocaine
Heart rate	↑	↑↑	↑↑	↓
Blood pressure	↑	↑↑	↑↑	↓
Respiratory rate	↑	↑↑	↑↑	↓
Hyperthermia	—	+	+	—
Altered mental status	—	±	±	—

^aIncludes benzodiazepines, barbiturates, and γ -hydroxybutyrate/ γ -butyrolactone

can follow a progression or occur independently. These aspects include alcoholic tremulousness, withdrawal seizures, hallucinosis, and DTs. These terms are preferred to the original terms described in the works of Victor and Adams [5] because they are less confusing. It may be more clinically relevant, however, to describe withdrawal as mild, moderate, or severe (life-threatening). Each aspect of alcohol withdrawal is discussed separately, with the understanding that they all are part of a single syndrome.

Alcohol withdrawal (previously called “alcoholic tremulousness”) typically begins within a few hours after cessation of drinking, when serum ethanol concentrations fall below a threshold level. This level varies with the degree of tolerance the patient has developed. The initial features are usually mild, and tremor is a common symptom. Other accompanying features variably include tachycardia, hypertension, diaphoresis, and anxiety [5, 6]. Intervention at this point may halt the progression or development of more significant symptoms and complications.

Alcohol Withdrawal Seizures

Alcohol withdrawal seizures (previously called “rum fits”) usually occur within 6–48 h after cessation of drinking, although they may occur later. The syndrome is typified by a single brief, generalized seizure with a short postictal period. Occasionally the patient has multiple short seizures over a brief period, but true status epilepticus occurs in less than 3% of cases [5]. Alcohol withdrawal seizures may be the initial manifestation of withdrawal and the sentinel event in approximately one-third of untreated patients who develop DTs [5].

Alcoholic Hallucinosis

In alcoholic hallucinosis, the hallucinations are typically visual or auditory and may be persecutory in nature. Onset is often within a few hours of abstinence. Alcoholic hallucinosis can occur independently of other signs or symptoms of withdrawal [5]. Although patients experience hallucinations, their mentation is otherwise clear. As such, the hallucinations often are disturbing in the otherwise functional and oriented patient.

Delirium Tremens

DTs is the best studied of all the withdrawal syndromes. The term *delirium tremens* not only applies to alcohol withdrawal but also serves as a model for all forms of sedative-hypnotic withdrawal (including GHB/GBL). Symptoms develop 24 h or more after the last drink and usually last 3–5 days [5]. As the name implies, *delirium* is an important aspect of DTs. During mild withdrawal, or shortly after a “rum fit,” the patient’s mental status generally is intact. An altered sensorium is one of the key distinguishing features of DTs. Patients may hallucinate, have seizures, and display extreme psychomotor agitation (tremens). Hallucinations can be visual or tactile (formication). Autonomic instability may manifest as hypertension, tachycardia, diaphoresis, miosis, and hyperthermia. Psychomotor agitation and autonomic instability associated with DTs represent the life-threatening aspects of alcohol withdrawal and should prompt aggressive therapy.

Sedative-Hypnotic Withdrawal

Sedative-hypnotic withdrawal (benzodiazepines, barbiturates, and GHB/GBL) may be clinically indistinguishable from alcohol withdrawal. The chronology may offer a clue, however, as to the etiology of the withdrawal. Because of rapid metabolism and the lack of active metabolites, GHB/GBL withdrawal generally occurs within 2–3 h of cessation of drug usage [32]. Seizures do not seem to be a common manifestation of GHB withdrawal. In a series of eight cases of presumed GHB withdrawal, only one patient had seizure-like activity, which was a preterminal event [32]. In this same series, patients had notable neuropsychiatric effects including paranoia and delirium, also the withdrawal syndrome was often protracted, and patients were given antipsychotics in addition to benzodiazepines (Grade III evidence). In contrast to the rapid onset of GHB withdrawal, diazepam has active metabolites, and withdrawal symptoms may not manifest for 1 week after cessation. Seizures are a common sign of benzodiazepine withdrawal.

Benzodiazepine withdrawal responds promptly to treatment with benzodiazepines (Grade II evidence), and GHB withdrawal may respond variable to this treatment. Other treatment options for GHB withdrawal include propofol and baclofen (Grade III evidence) [32].

Opioid Withdrawal

Opioid withdrawal can be divided into physical signs and symptoms and psychological symptoms. Piloerection, yawning, and lacrimation are some of the physical signs; nausea, vomiting, and diarrhea are common symptoms. These patients also have intense opioid craving associated with the feeling of being unwell. In contrast to sedative-hypnotic withdrawal, opioid withdrawal is associated with minimal autonomic instability. Patients may be slightly tachycardic and have minimal elevation in blood pressure, but this is partly in response to their physical and emotional symptoms. Opioid withdrawal is almost always associated with a normal mental status. Needle use in heroin abusers predisposes them to many infections, including CNS infections. Attributing fever and an altered mental status to opioid withdrawal could have catastrophic results. Opioid withdrawal, although thoroughly unpleasant, is unlikely to be life-threatening unless complicated by aspiration pneumonitis or complications of vomiting and diarrhea such as fluid and electrolyte abnormalities. The onset and duration of withdrawal secondary to opioid discontinuation depend on the agent in question. Heroin withdrawal can begin within 6 h of the last dose, peak by 48 h, and last 4–5 days. Although methadone withdrawal begins 2–3 days after the last dose and may last 2 weeks [33], iatrogenic opioid withdrawal can occur immediately after administration of an antagonist (such as naloxone or naltrexone) or a partial agonist (such as buprenorphine). This type of opioid withdrawal is most commonly associated with naloxone use and is short-lived as the duration of action of naloxone is limited (approximately 40–60 min) and usually requires no intervention. With withdrawal induced by longer-acting antagonists or

partial agonists, altered mental status may occur because of the abrupt, severe, and prolonged nature of the withdrawal.

Cocaine Withdrawal

Cocaine withdrawal is associated with an emotional component, whereas the existence of a physical component is debatable. The emotional component is associated with intense craving. This craving is the significant component of cocaine addiction and is the reason why detoxification from cocaine is more rehabilitation oriented. The “washed-out” syndrome that can occur after prolonged cocaine use may be interpreted as physical withdrawal symptoms. [34] Because this phenomenon is not prevented by continued cocaine use, defining it as withdrawal is debatable [35]. The chronic use of cocaine depletes presynaptic neurotransmitter stores, especially dopamine, leaving the user catecholamine depleted [36, 37]. As a result, baseline adrenergic activity is diminished, and patients may appear lethargic or adynamic with depressed vital signs. This effect usually is self-limiting and requires minimal if any supportive care.

Neonatal Withdrawal

Maternal addiction can lead to neonatal withdrawal. Time to clinical signs after birth varies with the agent in question. Neonatal alcohol withdrawal typically begins within 3 days of parturition and is manifested by opisthotonos, tremor, nystagmus, clonus, seizures, hypertonia, crying, hyperactive or asymmetric reflexes, excessive rooting (an oromotor reflex), diarrhea, vomiting, startle, and inability to thermoregulate [38, 39]. Opisthotonos and abdominal distention rarely occur in opioid withdrawal and can help differentiate the two when the mother is dependent on multiple substances. Although initially thought to occur only as a complication of fetal alcohol syndrome, neonatal alcohol withdrawal can occur independent of the fetal alcohol syndrome [39]. The presentation of neonates withdrawing from sedative-hypnotics would be indistinguishable. Regardless of the etiology, treatment remains the same.

The development of neonatal opioid withdrawal symptoms depends on the agent used by the mother. Heroin withdrawal typically begins in the first few days, whereas methadone withdrawal may not be evident for 10–14 days [40]. Neonatal and adult opioid withdrawal are similar. In addition to vomiting, diarrhea, irritability, yawning, sleeplessness, diaphoresis, lacrimation, tremor, and hypertonicity, neonates can have seizures, a high-pitched cry, skin mottling, and excoriation. These latter signs and symptoms are more typical of opioid withdrawal and rarely occur with neonatal alcohol withdrawal [38].

Differential Diagnosis

Most dependent users are skilled at treating their own withdrawal. While constructing a differential diagnosis for substance withdrawal, the clinician should try to elucidate the circumstances surrounding the patient’s withdrawal. Although lack of finances and lack of availability are common reasons to develop withdrawal, patients often have an underlying illness that prevents “self-medication.” An alcoholic patient may have pancreatitis, pneumonia, head trauma, CNS infections, or gastrointestinal hemorrhage [10]. Undiagnosed medical disorders may contribute significantly to mortality despite adequate therapy. Additionally, complications of alcohol withdrawal can be catastrophic. Besides hyperthermia and a myriad of metabolic complications, myocardial infarction may occur secondary to the physical stress associated with withdrawal.

Many disorders may be mistaken for alcohol withdrawal. Among them are thyroid storm, hypoglycemia, encephalitis, and to a lesser extent serotonin toxicity and neuroleptic malignant syndrome (Table 2). Also, certain toxins can mimic withdrawal symptoms. Sympathomimetic toxicity can present in a manner similar to sedative-hypnotic withdrawal, creating the same diagnostic dilemma. The anticholinergic patient may present with hallucinations, tachycardia, and hyperthermia. Symptomatic overdose of certain drugs may mimic substance withdrawal; these agents

include lithium, aspirin, and caffeine or theophylline (Table 3).

Diagnostic Studies

The diagnosis of withdrawal cannot be established without first excluding the other life-threatening disorders in the differential diagnosis. All patients in withdrawal should have serum analysis performed for standard chemistries, including glucose, magnesium, and calcium. Patients may have underlying metabolic derangements stemming from poor nutritional status or from vomiting and diarrhea. A complete blood count should be performed to assess the status of all cell lines because bone marrow suppression and occult hemorrhage are common afflictions in alcoholic patients. An elevated white blood cell count does not necessarily indicate infection, as it may be a marker of a stress response. Liver

function tests and coagulation assays are important in alcoholic patients, the latter to determine their synthetic function. A serum ethanol concentration may be a helpful prognostic tool because patients in alcohol withdrawal with elevated ethanol concentrations tend to have more severe withdrawal and are less likely to be compliant with outpatient detoxification programs [41].

A chest radiograph and computed tomography (CT) scan of the head are essential in the evaluation of the withdrawal patient with altered consciousness or seizures. A chest radiograph can help exclude pneumonia, whereas a CT scan of the brain can show subdural hematomas, cerebral edema, and other intracranial pathology that may be mistaken for delirium [42]. When symptoms are consistent with central nervous system (CNS) infection, a lumbar puncture is necessary to exclude the diagnosis. A CT scan of the brain also should be part of the evaluation of anyone presenting with new-onset seizure before the diagnosis of an alcohol withdrawal seizure is established [43]. An abdominal CT scan can help identify other disorders in the differential diagnosis of withdrawal, including pancreatitis, cholecystitis, and intestinal obstruction.

Treatment

In the past, numerous regimens were used to treat withdrawal. Mild withdrawal can be remedied by self-administration of the offending agent. When a patient is admitted for withdrawal or develops withdrawal as an inpatient, physicians must be aware of all treatment options. Logically, withdrawal responds best to reinstitution of the particular agent in question. Heroin and alcohol withdrawal present ethical dilemmas, however. Although some institutions may accept treatment of alcohol withdrawal with alcohol, most clinicians would find this treatment as enabling the underlying disorder, alcoholism [44]. Treatment with alcohol not only does not promote rehabilitation but also contributes to all the health risks associated with chronic alcohol use, including cirrhosis, pancreatitis, hepatitis, gastritis, and bone marrow suppression. The principle of cross-tolerance may be

applied in this instance. Benzodiazepines show therapeutic effect to varying extents for sedative-hypnotics, alcohol, and GHB/GBL. The safety and efficacy of benzodiazepine-based withdrawal therapy were borne out in studies performed in the mid-1970s [45]. Benzodiazepines are excellent anticonvulsants. Current practice guidelines for the treatment of alcohol withdrawal use benzodiazepines as first-line therapy (Grade I) [46].

Ethanol Withdrawal

Mild-to-moderate ethanol withdrawal usually responds well to low-dose oral benzodiazepines. Treatment regimens vary, and fixed-schedule treatments are common. Studies demonstrate, however, that “front-loading” benzodiazepines relieves withdrawal symptoms faster [47, 48]. In these studies, oral diazepam was given to patients in either a 10- or 20-mg dose at 1–2-h intervals until patients were asymptomatic. In one study, patients used one-third the amount of diazepam used with fixed-schedule therapy. More recently, as-needed chlordiazepoxide was compared with fixed-schedule dosing in a double-blind, placebo-controlled study [49]. Not only did the as-needed group require less chlordiazepoxide (100 Vs. 425 mg), but also total treatment time was reduced to 9 h from 68 h.

Moderate-to-severe withdrawal can be life-threatening and requires parenteral sedative-hypnotics or anesthetic agents. The use of the latter often necessitates endotracheal intubation. Dosing regimens are not well established and are highly variable. Most patients respond to conventional doses of benzodiazepines. Occasionally, larger doses are required to treat the withdrawal symptoms. If initial doses greater than 200 mg of diazepam or its equivalent are given to a patient without satisfactory effect, an alternative agent is often necessary (Grade III). Historically the barbiturates have been the second-line agent of choice [50]. Physician familiarity and established history are the major benefits of barbiturate therapy. Phenobarbital has a lag time to response that can make titration difficult, and the kinetics of

short-acting barbiturates may result in prolonged sedation when extended therapy is required (e.g., thiopental) [51]. However, a recent study demonstrated reduced ICU admissions for ethanol withdrawal patients who received a single dose of phenobarbital at the initiation of standard lorazepam treatment with no increase in adverse events [52]. Optimal therapy results in the patients being sedated and arousable but not obtunded or comatose. Whether regimens use benzodiazepines or barbiturates, prolonged therapy often leads to tolerance of the agent used. Tapering is required to prevent withdrawal from the therapeutic agent. Agents with longer half-lives or active metabolites, such as diazepam or chlordiazepoxide, may facilitate tapering.

In Europe, GHB has been studied for the treatment of alcohol withdrawal [53–55]. The investigators concluded that although effective, the use of GHB could not be recommended for all alcohol withdrawal patients. In the United States, GHB is restricted at this time. Similarly, carbamazepine has also been used in Europe for decades to treat alcohol withdrawal [56]. However, a systematic review of the use of carbamazepine and other anticonvulsants for alcohol withdrawal failed to show a significant benefit to this treatment modality over benzodiazepines [57].

Propofol has an increasing role in sedative-hypnotic withdrawal. It has been used for barbiturate and GHB withdrawal and has been studied for alcohol withdrawal (Grade II-3 evidence) [58, 59]. The benefits of propofol include rapid onset of sedation, rapid emergence when discontinued, and anticonvulsant properties. In addition to being a GABA agonist, propofol has NMDA antagonist properties [60]. This dual activity is similar to that of alcohol and may explain why propofol works well for patients refractory to benzodiazepines. Propofol withdrawal is not well described. However, propofol is a costlier agent than the other options discussed and has a narrow therapeutic index requiring close monitoring for respiratory depression. While propofol has great utility in intubated patients, benzodiazepines remain the mainstay of therapy. Ketamine is another anesthetic agent that has recently been evaluated as an

adjunctive treatment for alcohol withdrawal when combined with benzodiazepines (Grade III evidence) [61]. However, while an initial study suggests lower overall dosage requirements of benzodiazepine, the results have not been reproduced. Similarly, dexmedetomidine has also been studied as an adjunct to benzodiazepine treatment for alcohol withdrawal (Grade III evidence) [62]. Again, more research is needed on the adjuvant agents before formal recommendations can be made.

Other agents that have been used include antipsychotics, β -blockers, and clonidine [63, 64]. These agents are able to treat psychosis and autonomic instability but fail to treat the underlying disorder and as such are not recommended. These agents also may mask some of the symptoms associated with withdrawal, resulting in suboptimal treatment. Finally, although the use of neuroleptics in patients with psychotic symptoms seems logical, they are not cross-tolerant with sedative-hypnotics, lower the seizure threshold, exacerbate tachycardia, and impair heat dissipation. In animal models and case reports, neuroleptics, such as haloperidol, exacerbate sedative-hypnotic withdrawal [65, 66].

Sedative-Hypnotic (and γ -Hydroxybutyrate) Withdrawal

The principles of treatment for sedative-hypnotic and GHB withdrawal are based on alcohol withdrawal treatment. Although specific regimens for GHB withdrawal have not been developed, the goal of therapy is the same: restoration of autonomic stability, reduction of psychomotor agitation, and mild-to-moderate sedation. Duration of withdrawal varies with the specific agent involved (Table 4).

Opioid Withdrawal

Heroin (and other opioid) withdrawal is often treated with a medically acceptable opioid, such as morphine or methadone (Grade 1 evidence). Although methadone is available orally for

Table 4 Expected onset and duration of withdrawal symptoms by agent

Agent	Symptom onset	Duration
Alcohol	6–12 h	5–7 days
Alprazolam	24–48 h	4–5 days
Diazepam	5–7 days	Weeks
Lorazepam	2–4 days	Weeks
Heroin/morphine	4–6 h	3–5 days
Methadone	1–2 days	5–7 days
Butalbital	4–6 days	3–5 days
Phenobarbital	7–10 days	3–5 days
GHB/GBL	1–4 h	3–5 days

GHB/GBL, γ -hydroxybutyrate/ γ -butyrolactone

maintenance therapy, acute withdrawal should be treated parenterally (10 mg of methadone intramuscularly). The intramuscular route is preferable because these patients may be vomiting, and this route guarantees delivery of methadone. When methadone is unavailable or unacceptable, morphine provides a suitable alternative in the acute setting. An initial dose of 0.1 mg/kg intravenously followed by titration to response can provide symptomatic relief. Many oral opioids are available and can be dosed similarly using morphine equivalents. Iatrogenic withdrawal induced by naloxone is treated best by supportive measures only. Although unpleasant, the withdrawal is not life-threatening in an awake patient and is self-limited, often lasting less than 1 h. Other agents that have been used to treat opioid withdrawal include clonidine, benzodiazepines, and antiemetics [67–70]. A recent review of the literature related to clonidine use in the management of withdrawal syndromes (including opioid and alcohol withdrawal) suggests that while clonidine may be used as adjuvant therapy, further formal trials are needed to define best practice and dosing recommendations [71]. These agents treat some of the physiologic symptoms associated with heroin withdrawal; however, they do not relieve the intense craving, which may lead some patients to self-discharge. This may be a factor when deciding whether to use these agents alone or as adjuncts to opioid therapy. Long-term therapy in this subgroup of patients has developed into methadone and buprenorphine maintenance programs. These programs often combine counseling with high-dose

oral methadone (>100 mg) or buccal buprenorphine to prevent heroin use in these patients.

Summary

Familiarity with the terms *dependence*, *tolerance*, *cross-tolerance*, *addiction*, and *withdrawal*, coupled with an understanding of the pharmacology of the agents in question, not only facilitates the evaluation of patients in withdrawal but also enables appropriate management, decreasing morbidity and mortality in these patients. Substance abuse, which precedes withdrawal, is a multifaceted problem requiring a multidisciplinary approach. Although medical management of withdrawal may be sufficient initially, ultimately patients benefit from additional psychiatric and social counseling and support.

Background/Introduction and Possible Scenarios of Acute Radiation Injuries

Acute exposure to ionizing radiation can cause acute injuries in a variety of settings or during a number of scenarios (Table 1). Because these incidents are infrequent, health-care providers may not be familiar with the evaluation and management of the resulting potentially life-threatening illnesses. This chapter will discuss the evaluation and management of acute radiation syndrome (ARS) and will include a concise discussion of internal contamination with radioactive materials and its clinical consequences.

Definition and Types of Ionizing Radiation

Ionizing radiation is a form of energy that travels in space and that is able to remove an electron (i.e., ionize) from an atom upon interacting with it. Ionizing radiation emanates from the nucleus of “unstable” or radioactive atoms that decay to reach a more stable state. Radiation emission from the nucleus is termed disintegration. The number of disintegrations per second (termed activity of the source) is measured using the S.I. (Le Systeme International d’ Unités) unit Becquerel (Bq). The physical half-life of a radio-nuclide is the time it takes for the activity of a specific source to decrease by half through

Table 1 Examples of radiological/nuclear scenarios

Scenarios	Circumstances	Settings	Clinical impacts
Nuclear power plant accident	Accidental Intentional (less likely)	Occupational	Workers Public
Nuclear detonation (nuclear weapon or improvised nuclear device)	Intentional	Nonoccupational	Public
Radioactive dispersal device	Intentional Unintentional (less likely)	Nonoccupational	Public
Radiological exposure device	Unintentional (more commonly reported) Intentional	Occupational Nonoccupational	Workers Public
Transportation-related accident	Unintentional Intentional	Occupational Nonoccupational	Workers Public

Table 2 Physical, biological, and effective half-life of important radionuclides

Radionuclide	Physical half-life	Biological half-life	Effective half-life
Iodine-131	8 days	120–138 days	7 days
Cesium-137	30 years	110 days	108
Strontium-90	28 years	50 years	18 years
Polonium-210	138 days	~50 days	~37 days
Uranium-238	4.5 billion years	4 days	4 days

radioactive decay. Table 2 lists the physical half-life of a number of radionuclides.

The ionizing radiation that is emitted can be in the form of electromagnetic waves (i.e., gamma rays or X-rays) or particles (i.e., alpha and beta). Neutrons are a form of ionizing radiation that have wavelike and particle-like properties. Because of differences in electrical charge and mass, these different types of ionizing radiation vary in the distance they can travel in space, the ability to penetrate the body and irradiate internal organs, and the amount of energy they deposit on their path, which is termed linear energy transfer or LET. For example, alpha particles are positively charged, have a high LET, and will deposit the energy they carry over a short distance compared to gamma rays that are uncharged and have a low LET. Alpha particles are unable to penetrate the outer layer of the skin and therefore do not pose a radiation hazard when they are released from a radioactive source located outside the body. Gamma rays and neutrons are uncharged and therefore can penetrate the body

Table 3 Different types of ionizing radiation

Type of ionizing radiation	Travel in air	Ability to penetrate the body
Gamma ray	Several meters	Yes
X-ray	Several meters	Yes
Alpha particle	1 cm	No
Beta particle	1 cm	No
Neutron	Several meters	Yes

when they are emitted from a radioactive source located outside the body and can, therefore, irradiate internal organs and cells. Table 3 lists different types of ionizing radiation and their respective physical properties.

Radioactive atoms occur either naturally (i.e., uranium or radon) or are man-made in a reactor (e.g., cesium). People are continuously exposed to ionizing radiation emitted from natural sources such as radon or cosmic rays or man-made sources like nuclear power plants or medical diagnostic and therapeutic procedures (e.g., computed tomography scans or nuclear medicine procedures). On average, in the USA, one is exposed to 6.2 millisievert (mSv) of ionizing radiation annually [1].

Biological Effects of Ionizing Radiation

The biological effects of ionizing radiation result directly from interaction of the alpha or beta particles with DNA or indirectly from the production

of free radicals through gamma ray-induced hydrolysis of intracellular water. The clinical outcome of these biological interactions is divided into deterministic and stochastic categories. Deterministic clinical manifestations do not occur below a certain threshold radiation exposure dose. The higher the dose received, the more severe the clinical manifestations and the earlier they occur. Stochastic (derived from Greek – random) clinical manifestations can occur after exposure to any dose of radiation (i.e., there is no threshold). The higher the dose received, the greater the likelihood of the clinical manifestations, but the clinical effects are not necessarily more severe and they do not occur more rapidly. Acute radiation syndrome is an example of a deterministic clinical manifestation, whereas cancer is an example of a stochastic one. Different cells and tissues vary in their sensitivity to radiation: the Bergonie–Tribondeau law states that cells that are active mitotically or are undifferentiated are radiosensitive [2]. Lymphocytes are an exception because they are radiosensitive without being mitotically active [3]. Their sensitivity to the effects of radiation is not completely understood, but may be due to their high nucleus to cytoplasm ratio.

Lastly, the biological effect that results from a certain dose of radiation is greater when that dose is delivered more rapidly (i.e., higher dose rate). This is evident in radiotherapy where the patient tolerates very large (otherwise lethal) doses of radiation fractionated over several weeks [4].

Routes of Exposure to Ionizing Radiation

People exposed to ionizing radiation emitted from a source located outside their body are not contaminated with radioactive material and do not pose any hazard of secondary contamination or exposure to others. In contrast, patients can be externally contaminated with radioactive material that has deposited on their clothes, skin, or hair. These patients can transfer the material to others and cause secondary contamination. They can also secondarily expose people in their

proximity to ionizing radiation (i.e., gamma rays) emitted from the radioactive materials. It is important to highlight that people who are externally contaminated with a radioactive material that decays by emitting only alpha and or beta particles will not expose others in their proximity to ionizing radiation because the emitted particles are unable to travel a sufficient distance to deposit on another person. Radioactive material can also deposit inside the body and lead to internal contamination. This can occur by ingestion, by inhalation, or through wounds. Patients who are internally contaminated with radioactive material are exposed to the ionizing radiation emitted from these materials as long as they are inside the body (termed residence time) and as long as the material is radioactive (emitting radiation during the natural process of radioactive decay) [5].

The behavior of a radioactive element inside the body is governed by its chemical and not physical properties. In simple terms, the body does not know if the element is radioactive or not. Therefore, absorption, distribution, and elimination are not related to the radioactive properties of the element. Consequently, a radioactive element is subject to biological elimination and its corresponding biological half-life (Table 2) in addition to its radioactive decay and corresponding physical half-life. The effective half-life, which represents the combination of both processes, should be used when assessing radiation dose exposures received from an internalized radioactive element (Table 2) [6].

Radiation Units of Measurements

The amount of energy of ionizing radiation that is absorbed by the body or an organ is measured in the S.I. unit gray (Gy). Different types of ionizing radiation have a different health impact for the same dose of radiation absorbed by the body or an organ. This is referred to the dose equivalent and is measured using the S.I. unit sievert (Sv). A radiation weighting factor (K) is used to convert a radiation-absorbed dose to a dose equivalent. The K factor is 1 for gamma rays, X-rays,

and beta particles. For alpha particles the K factor is 20 and for neutrons it varies from 5–20 depending on the energy of the specific neutron [5]. In other terms, from the same dose of radiation absorbed by the body or an organ, an alpha particle is more “potent” than a gamma ray in terms of biological effects. Therefore, if a patient receives a dose of 1 Gy in the form of a gamma ray, then the dose equivalent is 1 Sv. On the other hand, if the dose received was in the form of alpha particles, the dose equivalent is 20 Sv [5].

Personal Protection Principles of Health-Care Providers at the Hospital

The following discussion assumes that patients have been screened for external contamination with radioactive materials and satisfactorily decontaminated at the scene by emergency medical services or upon arrival to the emergency department.

Professionals who care for patients who have been exposed to, or contaminated with, radioactive material inside the emergency department or in inpatient areas should follow universal or standard precautions. Protection from secondary contamination with radioactive material can be achieved by protecting the eyes, mouth, and respiratory system from dustlike materials. A surgical or N-95 mask is adequate, especially in the post-decontamination, hospital setting. Higher levels of respiratory protection, such as an air-purifying respirator or a powered air-purifying respirator, may be necessary on the scene or prior to the decontamination of a patient in the emergency department triage who is externally contaminated with radioactive materials [7].

Gamma rays that are potentially emitted from radioactive materials located inside or over the surface of a patient’s body will penetrate various protective suits including the ones used in Level A personal protective equipment. Providers can effectively decrease the radiation dose that they receive by minimizing the time they spend in proximity to the patient, maximizing the distance

and following standard precautions. These include hand hygiene measures and wearing goggles, a protective suit, and gloves. Distance is particularly protective because the dose of radiation is inversely proportional to the square of the distance from the source [8].

The use of lead aprons is not practical and may not be sufficiently protective from high-energy gamma rays [9].

Health-care providers should use personal dosimeters when caring for patients who are contaminated with radioactive materials. These could be in the form of passive detectors that need to be sent to a laboratory for analysis or digital detectors that are able to provide a real-time estimate of the dose received by the provider. Hospital radiology technologists and staff who are occupationally exposed to radiation (e.g., interventional cardiologists) routinely use these dosimeters to monitor their occupational exposure. The results of their monitoring are assessed and managed by the hospital radiation safety department and the radiation safety officer. For example, the US Occupational Safety and Health Administration annual dose limit for occupational exposure to the whole body is 50 mSv (Fig. 1).

There are no reported cases or incidents in which health-care providers have developed acute radiation illnesses after caring for patients contaminated with radioactive materials. In Goiania, Brazil, patients contaminated with radioactive cesium were cared for by providers for several days before the discovery of the incident (personal communication with Dr. Luiz Bertelli from the Los Alamos National Laboratory). None of these providers developed any radiation illness. Similarly, the monitoring of 37 health-care workers who cared for Alexander Litvinenko in London for 3 weeks prior to the discovery of his poisoning with polonium-201 did not reveal any significant secondary contamination [10].

Although biological samples of patient who are internally contaminated with radionuclides will be radioactive, the amount of radioactivity is minute, and the hazard to health-care workers is not significant as long as standard precautions are followed [10].

Fig. 2 Partial body exposure (Source: REMM)

Acute Radiation Syndrome

Acute radiation syndrome (ARS) is a complex disease that can be life threatening. It occurs in patients whose whole body (or a large part of the body) has received a dose of penetrating ionizing radiation that is greater than a threshold of approximately 0.5–1 Gy, over a short period of time (i.e., minutes to hours). Although some abnormalities can be detected in blood cells after exposure to whole body doses between 0.7 Gy and 2 Gy, ARS is not clinically apparent until the dose received is greater or equal to 2 gray.

When only part of the body is exposed, the patient is said to have received partial body exposure: unaffected cells can assist in the recovery of irradiated areas (Fig. 2 below from Radiation Emergency Medical Management website https://www.remm.nlm.gov/exposureimage_1.htm).

Additionally, when the dose rate is low and the dose is received over greater than 6 h, the normal physiological processes may repair the damage and the person can recover. When a patient is externally contaminated with a radioactive material that decays by emitting alpha or beta particles, and not by emitting gamma rays, the radiation is unable to penetrate the body and irradiate internal organs. In these cases, ARS will not occur. On the other hand, when the material is internalized and the dose is therefore delivered internally and is high enough (i.e., greater than 1 Gy), multiple organ dysfunction and ARS can occur. This occurred in Mr. Litvinenko, who was internally contaminated with polonium that decays by emitting primarily alpha particles [11].

The acute radiation syndrome has four phases: prodrome, latent, manifest, and recovery or death. As discussed above, ARS is a deterministic disease. The higher the dose received above the threshold, the more severe and the shorter the time course of the clinical illness. The dose of radiation that is expected to kill 50% of an exposed population within 30 days (LD50/30) without treatment is approximately 3.5–4.5 Gy. The LD100/60 is approximately 10 Gy [12]. With intensive medical therapy, the LD50/60 could increase. Similarly, the LD50/60 will be smaller when the patient has suffered combined injuries (e.g., trauma or burns) or has comorbid illnesses [13].

During the prodromal phase, the patient will develop nonspecific signs and symptoms due to the inflammatory response caused by the radiation

Fig. 3 Cellular kinetics for the hematopoietic syndrome as a function of days following exposure (Acute Radiation Syndrome in Humans from the Textbook of Military Medicine: Medical Consequences of Radiological and Nuclear Weapons, Borden Institute Publisher. Chapter 2, Page 20)

exposure. When the inflammation subsides, the patient enters the latent phase and feels better. During this time, rapidly dividing cells would have already died and new cells would have not been produced to replace them. Affected cell line will decrease in number and clinical effects become apparent in the manifest illness phase. For example, myeloid stem cells die after exposure to radiation and can no longer produce neutrophils. This will lead to neutropenia and its secondary complications such as infection. Cell lines with longer life spans like red blood cells (120 days) will need longer to manifest the secondary illness (i.e., anemia) (Fig. 3).

It is important to note that these phases are not discrete and some overlap will occur. Additionally, the higher the exposure dose, the more compressed the clinical timeline. For example, patients who are exposed to 30 Gy of radiation may go through the four phases and die within 24–48 h. In comparison, a patient who receives a dose of 4 Gy may develop ARS and recover after 4–8 weeks of therapy [14].

The clinical manifestations of ARS will therefore depend on several factors such as radiation dose and dose rate, the individual patient characteristics (e.g., age, comorbid illnesses, combined

injuries), the body area that was irradiated (e.g., whole body irradiation, partial body irradiation, shielding), and the time elapsed since exposure. In general, ARS consists of four sub-syndromes: the hematopoietic, gastrointestinal, neurovascular, and cutaneous sub-syndromes (Fig. 4).

When the dose received is between 2 and 6 Gy, the hematopoietic system is primarily affected and the patient develops the hematopoietic sub-syndrome. The neutrophil and lymphocyte counts will decrease and patients will develop bone marrow aplasia in subsequent days to weeks. The resulting pancytopenia predisposes the patient to infections, sepsis, bleeding, poor wound healing, and death [15].

When the dose of radiation received is greater than 6 Gy, the intestinal crypt cells are affected, which leads to denuding of the intestinal lining because of the inability to replace dying cells. Patients will develop the gastrointestinal sub-syndrome which manifests in vomiting, diarrhea, gastrointestinal bleeding, sepsis, electrolyte abnormalities, circulatory collapse, and death [15].

When the dose received is greater than 30 Gy, the patient can develop the neurovascular sub-syndrome. This sub-syndrome is not very

Fig. 4 Dose–response relationship of classic ARS sub-syndromes

well understood or characterized due to a paucity of clinical experience. Based on previous reports, affected patients develop altered mental status, seizures, coma, and cardiovascular collapse within minutes to hours after their radiation exposure and die 1–2 days later [15, 16]. The cutaneous sub-syndrome occurs when a dose of radiation greater than 2 Gray is deposited in the skin. The effects range with increasing radiation dose between early transient erythema, epilation, main erythema, dry desquamation, wet desquamation, late erythema, necrosis and ulceration. With the exception of the early transient erythema that occurs within the initial 24 hours after exposure, the cutaneous effects do not manifest until 10 days to several after the exposure [15].

It is particularly important to note that the clinical manifestations overlap and the duration of illness will vary greatly depending on the dose received and the individual clinical characteristics of the patient.

Recently, a different perspective on the pathophysiology of acute radiation syndrome has developed to include systemic effects that include, in addition to the classical four sub-syndromes, involvement of the lung, kidney, liver, and other organs and that occur at the higher dose ranges. Additionally, inflammation is thought to take a prominent feature of early radiation injury and prodromal manifestations which may serve as target of future therapies [17].

The assessment of the dose of radiation received by the patient has clinical and prognostic value. Initially, this assessment will be based on the exposure history, which includes the geographic location relative to the source of radiation, the signs and symptoms developed, and biological markers [15].

The time to onset of vomiting is commonly used as an initial rapid, albeit crude, method to assess the dose received. The higher the dose, the greater the likelihood of vomiting and the shorter the time to its onset. In general, patients who start to vomit within 4–5 h of their radiation exposure are likely to have received a dose greater than 1–2 gray and may develop clinical ARS. Patients who vomit or develop diarrhea within 1 h of exposure are expected to have received a dose greater than 6 Gy (Fig. 5).

Additionally, the rate of decline of the absolute lymphocyte count (ALC) can be used in dose assessment (Image Legend: Andrew's Lymphocyte Nomogram) (Fig. 6).

Resources permitting, an ALC should be obtained as soon as possible after the exposure and repeated every 8 h for 2–3 days then twice per day for the following 3–6 days [15]. A 50% decrease in the ALC during the first 24 h after exposure followed by a further steeper decline in the count over the subsequent 48 h is associated with a potentially lethal radiation exposure [15]. On the other hand, an exposure dose of 2–4 Gy,

Fig. 5 Relationship between time to onset of vomiting and dose over a range of 2–10 Gy (Reproduced with permission from the TMT Handbook Graph F30.b)

Fig. 6 Andrew's Lymphocyte Nomogram. From Andrews GA, Auxier JA, Lushbaugh CC. *The Importance of Dosimetry to the Medical Management of Persons Exposed to High Levels of Radiation*. In *Personal Dosimetry for Radiation Accidents*. Vienna: International Atomic Energy Agency; 1965. Extracted from the Centers for Disease Control and Prevention Website <http://emergency.cdc.gov/radiation/arsphysicianfactsheet.asp> Accessed on February 6, 2016)

which is below the LD50/60, will cause the ALC to decline over approximately 4–6 days [18]. The Radiation Emergency Medical Management website provides an online dose estimator [18] that can be used for time to onset of vomiting and serial ALC measurements. It is based on the Armed Forces Radiobiology Research Institute Biodosimetry Assessment Tool [19] and is available at http://www.remm.nlm.gov/ars_wbd.htm.

Additionally, the medical treatment protocol for radiation accident victims ("METREPOL") tool was developed in Europe to be used for the diagnosis and triage of people exposed to radiation in small and medium size incidents but not very large mass casualty incidents like an improvised nuclear device. This tool assigns patients to various response categories (RCs) using the severity of clinical manifestations in the critical target organs (hematopoietic, gastrointestinal, neurovascular, and cutaneous systems). This classification is repeated at regular time intervals that depend on the case severity. The RC is in turn utilized to guide medical management into one of several options that range from supportive care to stem cell transplantation [20].

The gold standard for assessing the dose of radiation received by a patient is the chromosome-aberration cytogenetic bioassay that uses the dicentric assay. This test can be performed at cytogenetic biodosimetry laboratories such as the one located at the Radiation Emergency Assistance Center/Training Site in Oak Ridge, Tennessee, USA [21]. Unfortunately, the assay is labor intensive and can require several days to complete. Some efforts have been made to increase test throughput by utilizing cytogeneticists who view the chromosomes remotely [22]. Additional biodosimetry tools and assays that utilize serum protein markers and gene expression are being studied. Electron paramagnetic resonance of nails or teeth is also being evaluated for its ability to estimate exposure

dose after a mass casualty incident. In general, several authorities have recognized the importance of combining a number of data sources (e.g., protein and genetic markers) when estimating radiation exposure dose in a patient. The use of electronic software to assist in data analysis has also been proposed [23].

Management of the Acute Radiation Syndrome

The management of acute radiation syndrome consists of supportive care, antiemetics, antidiarrheals, prevention and treatment of infections, blood products, colony-stimulating factors, and stem cell transplants in select cases. In addition, patients should be provided with neutropenic precautions similar to those who receive chemotherapy or transplantation.

Antiemetics are necessary to treat the nausea and vomiting that occur in patients with ARS. Serotonergic receptor antagonists such as ondansetron and granisetron are appropriate therapeutic options and are believed to be more efficacious and safer than prochlorperazine (Grade I evidence) [24–27]. Antidiarrheals like loperamide or diphenoxylate may also be necessary in patients with diarrhea (Grade III evidence) [28].

Antimicrobials should be administered to patients who have received a whole body dose of radiation greater or equal to 2 Gy and are at risk of becoming neutropenic. Oral fluoroquinolones are a reasonable initial choice in low-risk cases that are clinically stable and afebrile. Broad-spectrum antibacterials including parenteral agents are necessary in patients who develop fever, who are clinically unstable, or who develop severe neutropenia (absolute neutrophil count [ANC] < 500 cells/mm³). The therapeutic regimen should also include prophylaxis against herpes infections using acyclovir and antifungals in severe cases that do not respond to initial broad-spectrum bacterial coverage. Clinicians should consult with infectious disease specialists or refer to clinical guidelines for the management of neutropenia in cancer patients undergoing chemotherapy and published by professional societies such

as the Infectious Disease Society of America or the American Society of Clinical Oncology (Grade III evidence) [29, 30].

Blood products may be needed during the initial trauma resuscitation or during the following 2–4 weeks in patients who develop bone marrow aplasia and pancytopenia. Blood products should be irradiated to 25 Gy in order to prevent the occurrence of a transfusion-related graft versus host disease reaction. Blood products should also be leukoreduced to prevent febrile nonhemolytic reactions, lessen immunosuppressive effects of transfusions, decrease the risk of alloimmunization toward platelets, and lower the risk of transmission of cytomegalovirus infection [15].

Colony-stimulating factors are cytokines that stimulate surviving myeloid stem cells in the irradiated bone marrow. They are used for the hematopoietic sub-syndrome to decrease the severity and duration of neutropenia with the hope of decreasing mortality. These drugs have been shown to be beneficial and are used routinely in cancer patients receiving chemotherapy, in patients undergoing stem cell transplants, and in donors undergoing peripheral stem cell collection. The evidence supporting the use of these drugs in the hematopoietic sub-syndrome is limited to animal studies because of the inability to conduct randomized clinical trials in humans with ARS for both practical and ethical reasons. These drugs have been shown in animal models (e.g., rhesus macaques) to decrease the severity and duration of neutropenia and to increase survival after exposure to ionizing radiation (Grade III evidence) [31–33]. In 2015, the US Food and Drug Administration approved filgrastim (Neupogen[®]) and pegylated filgrastim (Neulasta[®]) for the treatment of radiation-induced myelosuppression and the hematopoietic sub-syndrome of ARS (Grade III evidence) (Table 4).

Other drugs with similar mechanisms of action are available and could potentially be used in an emergency (e.g., sargramostim, Leukine[®]; TBO-filgrastim, Granix[®]; and filgrastim, Zarxio[®]) (GRADE III). In the USA, the Food and Drug Administration could authorize these drugs under an emergency use authorization mechanism.

Table 4 Colony-stimulating factors approved by the US Food and Drug Administration for the hematopoietic sub-syndrome

Drug	US FDA indication	Dosage	Side effects and precautions
Filgrastim (Neupogen®) Grade III	Radiation dose ≥ 2 Gy, as soon as possible, preferably within 24 h of exposure	10 mcg/Kg s/c every 24 h until ANC > 1000 cells/mm ³ for three consecutive CBC or ANC > 10,000 cells/mm ³ after a radiation-induced nadir	Bone pain Sickle cell crisis in patients with sickle cell disease or trait Splenic rupture
Pegfilgrastim (Neulasta) Grade III	Radiation dose ≥ 2 Gy, as soon as possible, preferably within 24 h of exposure and a second dose 1 week after	Two doses, 6 mg each, administered S/C 1 week apart Dose is weight based in children weighing less than 45 Kg (refer to drug label)	Bone pain Sickle cell crisis in patients with sickle cell disease or trait Splenic rupture

A World Health Organization expert panel reviewed relevant literature and experiences [34–38] and made a weak recommendation for the use of allogenic matched stem cell transplant in specific patients who do not recover their hematopoietic function after 2–3 weeks of standard therapies, including colony-stimulating factors and who do not have limiting comorbid conditions or combined injuries (Grade III evidence) [39]. Therefore, stem cell transplant can be considered in specific situations and in consultation with experts in the field. The US Radiation Injury Treatment Network (“RITN”) is composed of approximately 64 transplant centers that are poised to assist in the management of patients with acute radiation syndrome, including those who require a transplant [40].

Depending on the specific emergency and the number of victims, resources can be scarce and standards of care may need to be altered. Medical providers may need to prioritize resources and medical countermeasures to patients with survivable injuries and provide palliative care measures to those who are moribund or have a poor prognosis for survival or recovery.

Delayed Effects of Acute Radiation Exposure

Patients who survive the acute radiation syndrome may develop delayed effects months to years later. This is due to the delay in manifestations that are

expected in slowly dividing cells. For example, cataract development is the most common delayed complication and has a variable latency period and severity (6 months to 35 years depending on the dose of radiation received and its dose rate). The current US annual occupational exposure limit to the eye is 150 mSv. Treatment is usually surgical replacement of the opaque lens [41].

Pulmonary disease that progresses from pneumonitis to pulmonary fibrosis may manifest month to years later in patients who have received a dose greater than 8 Gy to their thorax. Treatment of this potentially fatal disease is supportive [42].

Male and female sterility can also occur after exposure to ionizing radiation. The threshold for the development of temporary sterility in males is 1 Gy. The effect is usually temporary, and recovery occurs at variable times depending on the dose of radiation, age of the person, and gender (i.e., testes are more radiosensitive than ovaries) [43].

Internal Contamination

After externally contaminated patients are decontaminated to a satisfactory level, patients need to be assessed for internal contamination. This section will provide a brief description of the assessment and treatment paradigm for internal contamination. A comprehensive discussion is outside the scope of this chapter. In 2008, the

Table 5 Drugs approved by the United States Food and Drug Administration for the management of internal contamination with certain radionuclides

Radionuclides	Therapy and dose	Notes
Cesium or thallium	Prussian blue insoluble (Radiogardase®) Adults: 3 g PO every 8 h Children > 2 year: 1 g PO every 8 h	Can cause constipation, hypokalemia, and bluish discoloration of stools
Plutonium, americium, or curium	Calcium or zinc DTPA Adults: 1 g IV every 24 h Children: 14 mg/kg IV per day not to exceed 1 g per day	Calcium DTPA preferred during the first 24 h after internal contamination Zinc DTPA preferred in children and pregnant females
Tritium (H3)	Saline diuresis or water	Increasing glomerular filtration rate

National Council on Radiation Protection and Measurements published Report Number 161 (Management of Persons Contaminated with Radionuclides: Handbook) which is a valuable reference for this topic.

Internal contamination can be diagnosed by direct bioassay using a radiation detector placed outside the body if the radionuclide that has been taken up inside the body decays by emitting gamma rays [5]. This method cannot be used if the radionuclide decays by emitting only alpha particles or beta particles because these forms of ionizing radiation are not able to travel far enough in space to reach the detector. As an example, Alexander Litvinenko had a negative radiation detection survey because he was internally contaminated with polonium-210 that decays primarily by emitting alpha particles.

On the other hand, analysis of urine or fecal samples can detect radionuclides that decay by emitting gamma rays, alpha particles, or beta particles. This analysis is best performed on a 24-h urine sample to account for any diurnal variations in excretion. The US Centers for Disease Control and Prevention has developed assays that can utilize a spot urine sample to rapidly screen for internal contamination with a gamma, alpha, or beta emitter. This rapid screen can be followed with additional tests to identify the specific radionuclide and quantify the level of activity per unit volume of sample analyzed [44].

The quantification of the activity of a radionuclide present inside the body is important in order to estimate the dose of radiation that it will deliver

to target organs or the entire body over its biological and radiological life span, which is represented by the specific radionuclide effective half-life. If the dose delivered is greater than 250 mSv, the National Council on Radiation Protection and Measurements (NCRP) recommends long-term monitoring and decorporation therapy, if possible and available. To aid clinicians in making these determinations, the NCRP has created the clinical decision guide (CDG) which defines “the maximum once-in-a-lifetime intake (in Bq) of a radionuclide that represents a stochastic risk and avoidance of deterministic effects” [5].

The clinical manifestations of internal contamination depend on the physical and chemical properties of the radionuclides and the dose of radiation that would be delivered to specific organs, or the whole body, over the residence time of the radionuclide inside the body. For example, children or adolescents who were internally contaminated with radioactive iodine in the aftermath of the Chernobyl nuclear power plant accident had an increased risk of developing thyroid cancer [45]. Similarly, Alexander Litvinenko developed gastrointestinal distress followed by hair loss, bone marrow failure, and death within 3 weeks from his polonium-210 incorporation [11].

The management of internal contamination is primarily supportive. In the USA, a few drug therapies have been approved by the Food and Drug Administration to hasten the excretion and elimination of certain radionuclides from the body and therefore decrease the dose delivered to organs and the whole body over the duration of

their residence inside the person. These drugs are listed in Table 5.

Additionally, internal contamination with uranium salts can lead to renal toxicity that may be mitigated by alkalinizing the urine to a pH of 8 with intravenous or oral sodium bicarbonate for 3 days [1, 46] (Grade III evidence).

Patients who have received an internal dose that is greater than 250 mSv (i.e., have an activity greater than the corresponding CDG) need to be registered with the health department and undergo long-term follow-up and monitoring for delayed onset complications and illnesses like cancer.

Malignant hyperthermia (MH) syndrome is an unusual disorder. Much like an individual who has an allergy, the MH-susceptible patient is often unaware of his or her problem unless there is a family history of anesthesia-related problems that suggest MH or until exposed to the “triggering” agent. MH syndrome may not develop on all exposures. The resemblance to an allergy breaks down, however, on further analysis. MH is an inherited disorder [1]. Patients develop a hypermetabolic condition on exposure to drugs that are generally used to produce general anesthesia such as isoflurane, halothane, desflurane, and sevoflurane or skeletal muscle paralysis, namely, succinylcholine [2]. The pathophysiologic change in MH relates to an uncontrolled increase of intracellular calcium in skeletal muscle that leads to hypermetabolism, depletion of energy sources, acidosis, and membrane breakdown [1–3]. Untreated, MH syndrome is fatal in most cases. With prompt discontinuation of trigger agents and administration of the drug dantrolene [4], mortality may be close to zero [5]. This chapter discusses clinical presentation, pathophysiology, molecular genetics, diagnosis, treatment, and sources of information for this unusual cause of anesthetic morbidity and mortality.

History

MH was recognized in the early 1960s by clinical anesthesiologists and a clinical geneticist in Melbourne, Australia [6]. The event that attracted

their attention related to surgery for a young man who sustained a motor vehicle injury. The patient expressed great concern because many members of his family had died unexpectedly while under anesthesia. The anesthesiologists administered halothane anesthesia, and, warned by the patient’s concern, stopped the anesthetic and the procedure when the patient developed hypertension, then hypotension, tachycardia, and sweating. Michael Denborough, a consultant internist with an interest in inherited diseases, was called to investigate. He then described many salient features of the syndrome.

After Denborough and Lovell [6] described the syndrome, many others described similar cases throughout the world. By the end of the 1960s, the syndrome was called *malignant hyperthermia* or *malignant hyperpyrexia*. The reason for the appellation was the mortality of greater than 80% and the strikingly elevated body temperature that accompanied the disorder. Other peculiar features that were described included muscle rigidity, rhabdomyolysis, and in some cases, rigidity limited to the jaw muscles after the muscle relaxant succinylcholine was administered.

At the first international workshop on MH, held in 1971 in Toronto, Canada, clinicians and basic researchers began to exchange information about MH. Veterinarians and pig breeders reported that certain breeds of pigs developed what seemed to be MH on a regular basis when stressed [7]. The breeds were known for their muscle mass and included Pietrain, Poland China, and others.

Although there was great concern initially that MH-susceptible humans would develop the syndrome with stress, that has not been shown to be the case [2, 3]. However, some MH susceptibles may develop the signs of MH with vigorous exercise and exposure to heat [9]. There are many other differences between human and swine MH. The inheritance of the syndrome is autosomal recessive in pigs but autosomal dominant in humans. Nevertheless, the pig develops typical signs of MH on exposure to anesthetics that trigger MH. The pig has served as a useful model, however, for understanding the pathophysiology of MH, determining

Table 1 Landmarks in malignant hyperthermia

Demonstration that biopsied muscle responds with abnormal contractures to halothane and to caffeine [8, 10]
Recognition that all potent volatile anesthetic gases are triggers for MH, as is the depolarizing relaxant succinylcholine [2, 3]
Demonstration that local anesthetics and intravenous anesthetics are not triggers of MH [2, 3]
The finding, in 1975, that dantrolene sodium is a specific treatment for MH and the introduction in clinical use in 1979 in the USA [4, 11]
The routine use of capnography in anesthesia and the recognition that elevated end-tidal carbon dioxide is an early sensitive and specific sign of MH [2, 3]
The creation of patient advocacy groups, registries, and hotlines throughout the world to assist anesthesia providers and others to recognize MH and guide treatment
Demonstration that mutations in a specific gene that elaborates a calcium channel in muscle, the ryanodine receptor, are responsible for almost all cases of pig MH and perhaps 50% of human MH [1]
Development of a “knock-in” mouse model of MH incorporating mutations that predispose to MH [13]
Introduction of molecular genetic testing for MH diagnosis in limited circumstances
Demonstration that time from diagnosis to treatment is crucial in enhancing survival [14]
Demonstration that early detection and mitigation of hyperthermia reduces mortality [67]
Cataloging of over 300 DNA variants associated with MH in the RYR 1 gene. Demonstration that the CACNA1S gene is associated with MH in some cases
Demonstration of prevalence of RYR 1 variants associated with MH in 1 in 2000 people
Association of MH susceptibility with several myopathies such as central core disease, multimincore disease, nemaline myopathy, and others

MH malignant hyperthermia

which drugs precipitate the syndrome, and determining the effective treatment of MH.

Since the early 1970s, there has been an enormous growth in knowledge and awareness of how to diagnose and treat MH syndrome. Landmark advances are outlined in Table 1. All of these findings and many others have led to the reduction of mortality from MH to less than 7% in developed countries [5, 12].

In a sense, the term *malignant hyperthermia* has become a misnomer. Hyperthermia often follows other metabolic signs of MH and is often not manifest when the diagnosis is made.

Furthermore, with prompt recognition and treatment, the fatality rate of MH is low. The syndrome includes *anesthesia-induced myodystrophy* and *rhabdomyolysis of anesthesia*.

Incidence

MH, being an inherited myopathy, should be amenable to epidemiologic investigation of incidence, prevalence, and perhaps penetrance. However, the data have been difficult to gather. The reason is that MH patients in general have no specific phenotype, other than when exposed to anesthetic drugs or in special environmental stressors; the signs of MH during anesthesia may be nonspecific and mimicked by other processes, such as rapid absorption of carbon dioxide during laparoscopic surgery, fever, iatrogenic overheating, and myotonia. In addition, until the late 1998, there was no specific ICD-9 (*International Classification of Diseases – ninth revision*) code for MH, and the syndrome did not appear in the diagnostic databases of diseases.

The prevalence of MH is approximately 1 in 100,000 instances of exposure to general anesthesia, and the incidence of clinical signs that resemble MH but for which the diagnosis is not certain is 1 in 5000 instances of exposure to anesthesia [15]. In one small study, 25% of MH diagnoses based on ICD 9 or ICD codes represented an incident case of MH [16]. Overall, approximately 1000 cases of MH are diagnosed each year in the USA. In addition, the incidence of MH in children is about three times higher than in adults [17]. The incidence of clinical MH depends primarily on the use of the trigger agents for MH and the gene prevalence in the population. In the USA and Canada, a higher incidence of MH is found in Ontario, Wisconsin, and various locales where there are families who harbor the genetic change causal for MH. MH has been identified in every country and ethnic group where it has been looked for [12].

One study has determined that the incidence of susceptibility to MH in one province of Quebec is about 1 in 200 individuals [18]. That study was

performed because many patients in the province had been tested for MH susceptibility with biopsy (see under Diagnostic Testing). The province was settled by a small number of families in the nineteenth century, and there had not been a large admixture of other families in the province. A few families with MH accounted for most of the cases.

A study examining surgical discharge diagnoses in NY state found that MH was recorded in one in 100,000 discharges [19].

Recent studies have examined the prevalence of DNA variants of the principle gene that is causal for MH, the ryanodine receptor gene (RYR1). Studies in France and Japan and one in Germany described a prevalence of MH-causative mutations of one in about 2000 people [20], while a study of patients in the Baltimore/Washington area directly measured a prevalence of pathologic DNA changes in one in 400 people [21].

The understanding of the very low penetrance of the syndrome is a crucial question in managing patients and their families. A great deal of further investigation is needed to determine the epidemiologic characteristics of the disorder with accuracy. To the best of our knowledge, there are fewer than five deaths from MH among the approximately thousand MH episodes each year in the USA.

Pathophysiology

Malignant hyperthermia is a disorder of skeletal muscle biochemistry and physiology, yet in the absence of triggering agents, there are no identifiable signs or symptoms. No muscle abnormalities are consistently observed in MH-susceptible people. Only small subsets of subjects with MH, identified either by clinical presentation or diagnostic testing, show evidence of muscle disorders. These include patients with central core disease, multiminicore disease, King-Denborough syndrome, Native American myopathy, and late-onset myopathies [23–26]. It is doubtful that other tissues are primarily responsible for the clinical manifestations of MH. Based on the

recognition that muscle rigidity was a dramatic manifestation of most cases of MH, Kalow and colleagues tested muscle biopsy specimens from susceptible pigs and humans for their response to caffeine, the agent known to produce muscle contracture secondary to calcium release from the sarcoplasmic reticulum [8]. They found that the response to biopsied skeletal muscle to caffeine, *in vitro*, was clearly abnormal. Contractures developed in muscle tissue of MH-susceptible subjects with concentrations as low as 0.5 mM, not observed in normal muscle. MH muscle also showed significant (>0.5 g) contractures on exposure to clinical concentrations of halothane [27–29]. The same findings were not found in the examination of smooth or cardiac muscle (Figures 3 and 4).

Further refinement of understanding of the pathophysiology of MH has focused on the mechanisms responsible for calcium control in muscle. Several proteins mediate calcium release and control intracellular calcium levels. Most attention has been focused on the ryanodine receptor, a calcium channel which mediates excitation-contraction coupling in skeletal muscle (Fig. 2) [1, 22, 23]. Excitation-contraction coupling occurs when an action potential along the muscle cell's T-tubule membrane is converted into an intracellular chemical signal, via Ca^{2+} ion flow, which drives muscle contraction. Specifically, a conformational change occurs in the voltage-dependent L-type calcium channel, which in turn triggers activation of the ryanodine 1 (RYR1) Ca^{2+} release channel in the terminal cisternae of the sarcoplasmic reticulum. Most attention has been focused on the ryanodine receptor; however, alterations in several other calcium signaling mechanisms and at least six other genes have been implicated in MH [30–33]. Specific MH-associated mutations have been identified in only three genes to date: RYR1, CACNA1S, which encodes the α -1S subunit of the voltage gated L-type calcium channel of the T-tubule, and the STAC3 gene associated with Native American myopathy [85].

Further investigations using calcium-sensitive dyes and calcium ion electrodes showed markedly increased levels of intracellular calcium in whole

muscle or cultured muscle from MH-affected animals and humans on exposure to potent inhalational anesthetics [34–36]. The purported primary defect in MH is related to enhanced release and/or leak of calcium from the terminal cisternae of the sarcoplasmic reticulum (Fig. 1) [22]. Increased resting myoplasmic Ca^{2+} has been measured in several MH-causative RYR1 mutations; exposure of MH myotubes to ryanodine, which blocks *open* RYR1 channels, is without effect. In this model increased resting myoplasmic calcium is therefore not due to increased RYR1 calcium release but most likely to a mechanism called store-operated extracellular calcium entry (SOCE) [37]. Reuptake does not seem to be at fault in these tissues [38]. The consequence of enhanced release/leak of calcium is prolonged muscle contraction resulting from release of inhibition of actin-myosin interaction. Adenosine triphosphate (ATP) levels decline as a result of activation of processes to sequester calcium, leading to anaerobic metabolism and acidosis. Declining levels of ATP lead to breakdown of membrane integrity and release of intracellular enzymes, such as creatine kinase (CK), along with myoglobin, potassium, and hydrogen ions.

Recent research focus has been placed on a mechanism termed store-overload-induced calcium release (SOICR) as a possible etiology for MH. In this condition RYR1 spontaneously releases Ca^{2+} from the sarcoplasmic reticulum once luminal Ca^{2+} concentrations reach a critical concentration. New evidence suggests that mutations in RYR1 may lower the threshold for SOICR, thus causing spontaneous release or leak of Ca^{2+} [39]. A similar mechanism could be demonstrated in the RYR2-mediated, stress-triggered condition of catecholaminergic polymorphic ventricular tachycardia (CPVT). CPVT leads to bidirectional ventricular tachycardia and sudden cardiac death. Parallels can be drawn between the RYR1-mediated mechanism in MH and the RYR2-associated mechanisms in CPVT, in that they both reduce the threshold for store-overload-induced calcium release [40].

Another mechanism of RYR1 regulation via $\text{Ca}_v1.1$, a pore forming subunit of the L-type Ca^{2+} channel encoded by CACNA1S, has recently

Fig. 1 Activation of the contractile machinery in skeletal and cardiac muscles. **(a)** An action potential travels along an α -motor neuron to a group of skeletal muscle fibers and triggers an action potential in each of the muscle fibers. The action potential in turn activated voltage-sensitive dihydropyridine receptors (DHPR). The DHPR opens ryanodine receptors (RyR) by mechanical interaction, resulting in release of Ca^{2+} from SR and a transient increase in myoplasmic Ca^{2+} , which enables actin and myosin interaction and force development. SR (sarcoplasmic reticulum) Ca^{2+} -ATPase (SERCA) pumps Ca^{2+} back into SR and myoplasmic Ca^{2+} returns to resting levels and

the contraction ceases. **(b)** The activation of the Ca^{2+} -dependent contractile machinery is almost identical in cardiac muscle, with the exception of the Ca^{2+} release process. The cardiac action potentials last longer compared to skeletal muscle, which results in Ca^{2+} influx through DHPRs, and these Ca^{2+} ions induce opening the RyR and Ca^{2+} release from SR. The increase in myoplasmic Ca^{2+} enables actin and myosin interaction. Myoplasmic Ca^{2+} return to resting levels by SERCA-mediated pumping of Ca^{2+} into SR and extrusion of Ca^{2+} via the Na^{+} - Ca^{2+} exchanger (NCX) (From *Calcium Signaling*, Islam MS ed, Springer 2012)

Fig. 2 Location of ryanodine receptor type 1 (*RYR1*) mutations associated with malignant hyperthermia susceptibility and central core disease. Mutations found in European and Australian malignant hyperthermia-susceptible/central core disease families are shown at the top; mutations in North American malignant hyperthermia-susceptible/central core disease families are shown at the bottom of the diagram. The mutations reported only in North

American MHS families and *RYR1* variants identified in North American MHS subjects are shown in bold. The three mutational hot spot areas are shadowed. CaM, calmodulin; DHPR, dihydropyridine receptor; FKBP 12, FK 506 binding protein 12. Diagram courtesy of Dr. N. Sambuughin. (Reprinted, with permission, from Anesthesiology, second edition. Longnecker DE et al., eds. McGraw-Hill, New York, 2012)

been elucidated. $\text{Ca}_v1.1$ activates RYR1 during excitation-contraction coupling, but it also suppresses the leak of Ca^{2+} ions from the sarcoplasmic reticulum when RYR1 channels are at rest. Disruption of this inhibitory regulation may explain increased sensitization of muscle cells to MH triggers [41].

Recent work by Eltit et al. [42] demonstrated that nonspecific sarcolemmal cation channels can cause Ca^{2+} and Na^+ overload both at rest and during an MH crisis [42]. Utilizing a knock-in mouse model, the study showed an overexpression of nonspecific sarcolemmal cation channels associated with influx of extracellular calcium and elevated resting intracellular calcium and sodium in the MH group. Halothane resulted in further increases in myoplasmic sodium and calcium in the MH animals.

Evidence of abnormal calcium control in MH-susceptible patients, even without exposure to anesthetic agents, is suggested by nuclear magnetic resonance studies in exercising human muscle in vivo [43–47]. These studies show greater inorganic phosphate levels at rest and with exercise, exercise-induced acidosis, and slower recovery of ATP levels in MH-susceptible patients. These changes do not lead to clinical signs of MH.

Although mutations in the ryanodine receptor appear to be an important factor in the pathophysiology of MH, only about 50–70% of MH-susceptible families have been linked to ryanodine mutations [1, 48]. The presence of a mutation also does not explain the interindividual and intraindividual variability in the clinical expression of MH syndrome. In several families, there has been discordance between the MH

Fig. 3 In vitro contracture response. Cut muscle bundles from the vastus muscle weighing approximately 150 mg are mounted in a temperature-controlled bath. The muscle is stimulated at 0.1 Hz with a supramaximal stimulus. Halothane 3% in 95% oxygen and 5% carbon dioxide are introduced into the bath. (a) 3 g contracture typical of malignant hyperthermia susceptibility. (b) Normal response to halothane

ryanodine genotype and phenotype as determined by the in vitro caffeine halothane contracture test (IVCT) [49–53].

Central core disease, a dominantly inherited neuromuscular weakness, is one of the myopathies strongly associated with MH, and mutations in the ryanodine receptor have been shown to be the most common cause for central core disease [54, 55]. Hypokalemic periodic paralysis is another myopathy that has been associated with mutations in the dihydropyridine receptor in the same region as mutations related to MH [56]. Some patients with these disorders have displayed clinical MH reactions, whereas others have not.

The fine details of calcium control and its alteration in MH patients require further study and examination to better characterize the clinical presentations of MH. As the field of molecular genetics is rapidly advancing, we can anticipate identification of new MH-causative genes and greater sensitivity and efficiency of genetic testing. Continued growth of genetic databases will be of great use for better understanding of the genotype/phenotype relationships in MH. There is a lot more to be learned about the exact mechanisms of MH. Nevertheless, the basic finding that MH

results from a hypermetabolic response to increased levels of intracellular calcium in skeletal muscle in genetically predisposed patients exposed to potent inhalational agents and/or succinylcholine remains an essential tenet of the pathophysiology of the disorder.

Diagnostic Testing

After the demonstration that biopsied skeletal muscle behaved abnormally on exposure to caffeine and to halothane [27, 28] in vitro, a standardized testing protocol to diagnose MH was developed. There are three major testing protocols in common use throughout the world [12]. The protocols in Europe [27] and North America [28] are similar [29]. The one in Japan is different [60].

In protocols using muscle bundles (Europe and North America) weighing about 100 mg, the tissue is tested on the same day as harvest. The muscle tested is either the vastus lateralis or the vastus medialis. Tests are conducted in duplicate or triplicate. The muscle is electrically stimulated to produce contractions of at least 0.5 g. Exposure to caffeine and to halothane results in contracture development (Figs. 3 and 4) in MH-susceptible individuals.

Fig. 4 Responses to caffeine in vitro. Same preparation with different muscle bundles as in Fig. 3 except the muscle bundle is exposed to incremental concentrations

of caffeine for 4 min each. A positive response indicating malignant hyperthermia susceptibility is a contracture of 0.3 g or more to 2 mM of caffeine

In the European protocol [58], exposure to halothane is done in increments of 0.5%, 1%, and 2%. A positive response is a contracture of at least 0.2 g on exposure to 2% or less of halothane (see Fig. 3). Other strips are exposed to incremental doses of caffeine (0.25, 0.5, 1, 1.5, 2, 3, and 4 mM), and a positive response is 0.2-g contracture to 2 mM of caffeine or less (see Fig. 2). If the response to both agents is positive, the patient is considered *MH susceptible*. If the test is positive to only one agent, the patient is designated as *MH equivocal* but for clinical purposes is considered as *MH susceptible*.

In the North American protocol [59], the exposure is to 3% halothane, and a contracture

of 0.5 g or greater is considered positive. Exposure to caffeine is essentially similar to that in Europe except that the concentrations are 0.5, 1, 2, 4, 8, and 32 mM. A contracture of greater than or equal to 0.3 g at 2 mM of caffeine is considered positive. Patients are considered *MH susceptible* if the response to one of the agents is abnormal.

Multicenter studies have shown a sensitivity of close to 100% [27, 28] but a specificity of about 82–93% in Europe [16, 28] and 78% in North America. In both tests, considerable interlaboratory variability is noted – not surprising, given that these are biologic tests. Because 5–15% of responses are considered equivocal by the European test, alternative agents have been

used. Responses to ryanodine [29, 57] and to chlorocresol [61] have been shown to be abnormal in MH muscle.

There are five biopsy centers for MH in North America (Table 2) and more than 20 in Europe. Other biopsy centers exist in other countries, including Australia, New Zealand, Brazil, and Israel. The test is time-consuming and expensive to perform. Despite the promise of other testing procedures, such as determination of high-energy phosphate depletion with exercise in vivo as measured by nuclear magnetic resonance spectroscopy [43–47], the biopsy response to caffeine and halothane remains the gold standard diagnostic test.

In Japan, the diagnostic test also uses skeletal muscle, but muscle in which the sarcolemma has been chemically removed [60]. Such skinned muscle showed accentuated responses to calcium and to caffeine. However, comparison between the skinned muscle test and IVCT test using whole muscle bundles showed a discordance between the two tests. As a result, biopsy centers in Europe and North America have decided not to employ this test [62].

Histologic examination of the biopsied muscle usually reveals nonspecific findings, such as type 1 atrophy, internal nuclei, and variation of fiber size. A few patients show changes consistent with central core or minicore disease, however [63]. Aside from this occasional finding, there is no distinctive pathologic change in MH muscle

[64]. For diagnostic purposes, the patient must be sent to a biopsy center for testing.

With the demonstration of the association between *RYR1* mutations and MH susceptibility in certain families [1, 29], many believe that routine testing for ryanodine mutations has become essential [65]. Some investigators believe that if a known mutation in *RYR1* is found in a family member, other family members showing that mutation may be confirmed as MH susceptible. Further investigation is needed to rule out susceptibility if the mutation is not found in a family member. This is a promising and exciting prospect for simplified diagnosis of MH [27]. In Germany and in Australia, where several families have been identified and screened for *RYR1* mutations, 25% of families can be characterized by a *RYR1* mutation [66]. Family members may be evaluated by DNA testing for susceptibility to MH.

The virtue of molecular genetic testing is the high specificity and the fact that DNA may be harvested from white blood cells or buccal cells. Many other less invasive tests are in development. These include measurement of carbon dioxide production after microinjection of caffeine into muscle [67] and calcium release measurement on exposure of cultured muscle cells to halothane. B lymphocytes also manifest activity of the ryanodine receptor, and the calcium flux changes that are found in muscle may be shown in isolated B lymphocytes. Another study has demonstrated enhanced release of adenosine in B lymphocytes from MH susceptibles [68].

Consultation with an MH biopsy center director, a member of the professional advisory council of MHAUS and/or genetic counselor is advisable prior to referral for diagnostic testing.

Clinical Presentation

The clinical diagnosis of MH may be easy and straightforward or challenging. MH may be precipitated during surgery on exposure to the potent inhalational anesthetic agents and/or succinylcholine only. Other drugs used in anesthesia to produce insensibility or muscle paralysis are not triggers for MH (Table 3).

Table 3 Safe and unsafe pharmacologic agents in malignant hyperthermia

Malignant Hyperthermia Triggers
Succinylcholine
All potent inhalational anesthetics
Halothane
Desflurane
Sevoflurane
Isoflurane
Enflurane
Methoxyflurane
Ethers
Agents that do not trigger malignant hyperthermia
Nitrous oxide
All local anesthetics
Intravenous anesthetics (e.g., thiopental, etomidate, propofol, ketamine, dexmedetomidine)
Nondepolarizing muscle relaxants (e.g., curare, rocuronium, vecuronium, atracurium, cisatracurium, mivacurium, pancuronium)
Opioids (e.g., morphine, fentanyl, sufentanil)
Anxiolytics and benzodiazepines
Reversal agents (e.g., naloxone, flumazenil, anticholinesterases, anticholinergics)
Mixed opioid agonists/antagonists (e.g., nalbuphine, buprenorphine)
Droperidol/haloperidol

In the past, MH most often occurred shortly after induction of anesthesia and was marked by a paradoxical rigid response to succinylcholine, with tachycardia, hypertension, increase in end-tidal carbon dioxide, and fever [1–3]. Although this scenario still occurs, as anesthetic practice has evolved and succinylcholine use has declined, the manifestations of MH have also changed. MH now occurs later in the course of anesthesia and even in the recovery room [69].

The earliest, most sensitive, and specific sign of MH is an increase in end-tidal carbon dioxide that requires large minute ventilation to control. Patients who require two or more times predicted minute ventilation to maintain normocarbica are hypermetabolic. End-tidal carbon dioxide may increase to 50 or 100 mmHg during MH episodes. Besides MH, other causes of hypermetabolism

include sepsis, iatrogenic overheating, faulty monitor function, and rarely thyrotoxicosis or pheochromocytoma (see later discussion of differential diagnosis of MH). Tachycardia is also an early sign of MH, but the differential diagnosis of tachycardia is extensive.

Hyperthermia is often considered a late sign of MH, but recent studies demonstrate that this is not the case. It is one of the three most common early signs of MH [70]. If the patient's body temperature has increased to 40 °C (104 °F), early signs of MH have been missed. If core temperature exceeds 42 °C, disseminated intravascular coagulation almost always supervenes, leading to a high fatality rate. It is vital to monitor a patient's core temperature during all general anesthesia exposures lasting longer than about 20 min. Hyperthermia is sometimes an important tip-off to the diagnosis of MH. A recent study demonstrated that the mortality from MH is increased 13-fold when core temperature is not monitored [70]. All patients undergoing general anesthesia lasting for 30 min or more should have core temperature monitored (esophageal, tympanic, bladder, pulmonary arterial or nasopharyngeal). Other sites of temperature monitoring are not as indicative of core temperature.

Muscle rigidity during anesthesia exposure is another important, specific sign for MH [71]. One of the common forms of muscle rigidity that has been noted in MH is masseter muscle rigidity after the use of succinylcholine. Of children anesthetized with an inhalational agent followed by administered succinylcholine, 1% develop masseter muscle rigidity [72–74]. Clinical MH follows in about 20% of cases, but the onset may be delayed. It is not clear why some patients who are not MH susceptible also develop succinylcholine-induced muscle rigidity. When there is generalized muscle rigidity, MH is almost certain. Masseter rigidity along with generalized rigidity is virtually pathognomonic for MH [75].

Rhabdomyolysis is another characteristic feature of MH [76]. CK elevation may be dramatic and extreme, whereas myoglobinuria may occur soon after the onset of the MH episode.

Myoglobinuria and CK elevation peak at about 14 h after the episode, however, and repeated determinations of CK are needed to diagnose MH or confirm the suspicion of MH. An easy screening test for myoglobin is urine dipstick for blood in the absence of red blood cells. In some cases where MH is detected early and treatment begun promptly, elevation of CK may be minimal.

Hyperkalemia and hypocalcemia are the typical electrolyte changes during an MH episode. Hyperkalemia may lead to arrhythmias. Hyperkalemia sufficient to cause ventricular fibrillation or asystole has been reported after the use of trigger agents in patients with a wide variety of myopathies, especially central core disease, muscular dystrophy, and various forms of myotonia.

Nonspecific signs of MH include tachycardia, tachyarrhythmias, tachypnea, sweating, hypertension, and hypotension. Coagulation abnormalities are more common in patients experiencing marked hyperthermia. Arterial blood gas analysis is essential in confirming the diagnosis of MH in many cases. Typically, respiratory and metabolic acidosis are found. Hypoxemia is not common during MH. Venous blood gas is a good substitute for arterial sampling. Elevation of venous carbon dioxide tension and marked acidosis are seen during MH crisis.

The presentation of MH may consist of a mixture of all of the abovementioned signs or may be limited to only a few, making the diagnosis challenging. When MH is suspected but not easily confirmed, it is advisable to treat with dantrolene, control the metabolic signs, and investigate the patient later. Table 4 lists common signs of MH and their incidence.

Table 4 Signs of malignant hyperthermia

Signs	Incidence (first 30 min) (%)
Tachycardia	90
Hypercarbia	80
Rigidity	80
Hypertension	75
Hyperthermia	70

Time of Onset

Most episodes of MH occur in the early part of the anesthesia exposure, certainly within the first few hours. Late-onset postoperative rhabdomyolysis is unlikely to be MH, but frequently there are not enough data to allow a true differential diagnosis. Perioperative rhabdomyolysis or myoglobinuria may occur in patients who are not susceptible to MH [77].

Normal patients who are not susceptible to MH may experience tenfold to 100-fold increases in serum myoglobin [78] after succinylcholine; repeated administration (i.e., intermittent intravenous bolus) is associated with more prominent increases in myoglobin level. Other causes of perioperative rhabdomyolysis include (1) pressure-induced muscle ischemia from prolonged surgical positioning [79], (2) muscle ischemia from prolonged tourniquet inflation [80], (3) extensive soft tissue trauma, (4) electrical injury, and (5) underlying myopathy/enzymopathy (such as CPT2 deficiency) [81] or metabolic disorder, rendering muscle more susceptible to injury from ischemia, fever, or fasting. It is difficult to exclude MH from consideration with confidence unless the medical record clearly shows absence of hypermetabolism during anesthesia and in the early postoperative period. If the patient later undergoes a biopsy and is found to be MH susceptible by the caffeine halothane contracture test, there is a tendency to assume the episode was MH related. For example, if a patient develops flank pain and rhabdomyolysis starting more than 24 h after an uneventful 8-h anesthetic, and the subsequent caffeine halothane contracture test is positive for MH, it is possible that the patient is not truly MH susceptible [82]. It may be more likely that rhabdomyolysis was caused by skeletal muscle ischemia associated with intraoperative positioning, a previously subclinical metabolic myopathy, or morbid obesity. Whether this was an MH event is highly debatable, although based on contracture test results, the patient should be considered as MH susceptible. In the absence of other specific causes of rhabdomyolysis, such as

sepsis, the patient should be referred for neurologic evaluation for the presence of an occult myopathy or enzymopathy.

Malignant Hyperthermia-Like Conditions

Sudden Cardiac Arrest and Myopathies

In the early 1990s, a series of young, mostly male patients developed unexpected cardiac arrest soon after the induction of anesthesia or in the recovery room, and their cases were reported to the MH hotline [83]. Further investigations of these cases revealed that the patients were harboring myopathies that had not produced clinical signs and symptoms prior to the administration of anesthetic agents. The cardiac arrest in these cases was related to hyperkalemia, whereas hyperthermia, tachycardia, and muscle rigidity were not constant features in all of them. Rhabdomyolysis was, however, common.

After analysis of those events, the younger patients were identified as having classic Duchenne muscular dystrophy, whereas the older patients were found to have Becker's muscular dystrophy [83].

Since then RYR1 mutations have been implicated in a variety of inherited myopathies, and it has been increasingly important as well as difficult to delineate whether and to what extent these myopathies can predispose patients to an MH episode.

Increasing numbers of RYR1-related myopathies are being defined and added to the expanding spectrum of congenital myopathies. Along with the dominantly inherited core myopathies (e.g., central core disease and multiminicore disease), a growing collection of recessive noncore myopathies, with varying mutations along the RYR1 gene, are being investigated [84]. Mutations in RYR1 are considered the most common cause for inherited neuromuscular disease and are associated with a wide range of clinical symptoms from MH susceptibility to clinically recognized congenital myopathies.

Other, non-RYR1 related core myopathies are under investigation. Among them is a rare

myopathy associated with dysmorphic features and MH susceptibility found among patients of Native American heritage. A recessive mutation on the STAC3 gene, which is a component of the excitation-contraction coupling machinery, was isolated in these patients [85]. This myopathy has also been found in individuals who are not Native Americans (Jerome Parness, M.D., Ph.D., Dept. of Anesthesiology, University of Pittsburgh School of Medicine, "personal communication").

Most pediatric anesthesiologists have phased out the routine use of succinylcholine after a black box warning issued by the US Food and Drug Administration ordered a change in the package insert stating that it should be administered in children and young adults only in situations where the patient has a full stomach or a difficult airway. Rapid-onset nondepolarizing agents have largely replaced succinylcholine in the operating room and should be considered for routine use for intubation in the emergency department as well as intensive care units.

Awake Malignant Hyperthermia

MH in the awake state is much harder to diagnose than MH in the operating room. A large increase in the production of carbon dioxide in an immobile and anesthetized patient is unusual. The cold operating room, depression of thermoregulation, and frequent use of neuromuscular blockade make the classic signs and symptoms unusual except in an MH episode. Even patients who are febrile from bacteremia usually lose heat and reduce metabolic rate under anesthesia. Therefore clinical signs frequently suggest the diagnosis of MH early in the disease process in the operating room. The diagnosis can then be confirmed with laboratory tests and subsequent muscle biopsy for IVCT.

Increasing numbers of non-anesthetic-related or awake MH cases have been reported in the last decade. Some of these are related to extreme exertion during sport or exercise [86–88], heat stress [89–91], and sudden death [92]. As we gain more insight into RYR1-mutation-related conditions, it is becoming apparent that sequelae seen with MH can often be seen without the traditional triggering agents. For example,

a recent case report of recurrent fever-induced rhabdomyolysis in a patient who had never been exposed to anesthesia, but was subsequently found to have a novel mutation in the RYR1 gene, highlights this overlap [93]. A study of 39 families with cases of rhabdomyolysis and/or exertional myalgia found nine heterozygous RYR1 mutations in 14 families, further strengthening our understanding of the link between inherited neuromuscular disease and the possibility for malignant hyperthermia susceptibility [94].

Conditions that overlap in their presentation and/or genetic mutations will be discussed in greater detail in the following paragraphs. Suffice it to say here that they may not represent MH in many instances, and they are harder to recognize, diagnose, classify, and sometimes treat than a true “classic” MH case. Even the postoperative patient, who awakens from anesthesia shivering, who may or may not have been febrile preoperatively, is much more difficult to evaluate for MH susceptibility. Although most patients awaken with little to suggest hypermetabolism, many who are hypothermic in the operating room shiver on awakening. This shivering may be confused with evidence of MH [95], even though shivering or rigors are not signs of MH; shivering is frequently treated with low-dose meperidine or acetaminophen. MH is ruled out if this treatment results in lysis of fever. Some patients emerge from anesthesia with excitement and agitation and may need physical restraint. As a result there may be abnormal laboratory results such as lactic acidosis or elevated CK levels. This response, although uncommon, is still more frequent than the incidence of MH in the population (1 in 10,000). Most such patients are not MH susceptible [96, 97] based on IVCTs.

Non-anesthetic Drugs and Circumstances

While MH is often not recognized right away in the operating room, it is even harder to diagnose in the patient who has not had an anesthetic at all or who is more than 24 h postanesthetic; confirmed postanesthetic MH episodes present within 1 h

after discontinuation of anesthesia. In many instances MH is not immediately considered, especially if there is no personal or family history of MH. Aside from cases related to exertion and heat stress, non-anesthetic drugs and consumption of illicit substances have been implicated in triggering MH-like episodes.

Not everyone agrees that these cases are truly MH. Even with a positive IVCT, given its 10–20% false positive rate, a definitive MH diagnosis is uncertain. The more we understand the molecular genetic components and the biochemical mechanisms behind MH, as well as the mechanisms behind uncontrolled temperature elevation and rhabdomyolysis, the more we begin to see a multiplicity of subtypes and possible cumulative stressors and situations capable of triggering an MH-like episode.

Cocaine, for example, does not cause *in vitro* contracture of MH-susceptible muscle, and it does not change the response to low concentrations of halothane [98]. Intrinsic myotoxicity or direct stimulation of muscle metabolism also does not seem to be a factor. But *in vivo*, cocaine may potentiate triggering agents via its many effects on catecholamines, central excitation, and temperature regulation.

Because MH-susceptible muscle is known to be more sensitive to caffeine *in vitro*, one concern often raised is whether patients who are MH susceptible should avoid caffeine or the other methylxanthines such as theophylline. Sufficient evidence seems to have accumulated to indicate that both are safe at doses that are not toxic in normal individuals. Based on *in vitro* studies, it is possible that triggering agents will be more likely to cause an MH episode in patients who exhibit high levels of these agents [99].

Amide local anesthetics were previously thought to be harmful, because lidocaine may enhance *in vitro* contracture by inhibition of calcium sequestration into the sarcoplasmic reticulum. Reexamination has shown that lidocaine does not trigger MH in susceptible swine, even when given in doses above the convulsive threshold [100]. All local anesthetics, including the amides, are currently considered acceptable for anesthetic purposes [101, 102].

Other drugs and compounds have been suggested as triggers of MH or MH-like effects. A link between statin myopathies and MH is currently under investigation, since mutations in muscle disease genes, including RYR1, have been shown to exist in patients with statin induced myopathy [103]. It is still unclear whether statins pose a risk for MH during anesthesia in MH-susceptible patients. It appears reasonable to either avoid statins altogether in patients with MH susceptibility or, at the very least, be watchful for symptoms of rhabdomyolysis when statins are initiated in such patients.

Chlorocresol, a preservative in many drugs, is a potent, specific trigger in the IVCT [104] and is a trigger in vivo in susceptible pigs. However, large doses need to be given over a short period of time to see in vivo triggering. Since such high blood levels are close to the toxic dose in all animals, it is not likely that enough preservative to trigger an MH episode will ever be present in the blood stream [105]. For example, greater than 100 units *per kilogram* of insulin would contain the threshold dose of preservative to trigger MH.

Centrally acting agents, such as serotonin agonists and neuroleptic drugs, may produce a syndrome comprised of fever, acidosis, and rhabdomyolysis that resembles MH. Caroff and associates reported a high incidence of positive response to the IVCT in seven patients with previous NMS [106]. In contrast, Bello and coworkers reported normal IVCTs in 29 of 32 patients with previous NMS [107]. One should therefore not automatically assume that patients with NMS are MH susceptible, and to do so could put them at risk. Patients with severe NMS may benefit from electroconvulsive therapy, and the optimal anesthetic technique for this procedure includes the triggering agent succinylcholine. The rare possibility of an MH episode does not warrant prohibition of the use of succinylcholine in patients with acute NMS unless they are already exhibiting signs of rhabdomyolysis. Even though the pathophysiology of NMS is distinct from MH, dantrolene may benefit patients via reduction or abolition of muscle rigidity, temperature reduction, and attenuation of rhabdomyolysis [108].

A mention of methylene blue and its ability to act as an MAOI inhibitor is warranted in this section. The use of methylene blue in conjunction with a selective serotonin reuptake inhibitor has led to fatal toxicity in the postoperative setting, in part because the general anesthesia may have delayed or attenuated the typical presentation of serotonin syndrome and led to a protracted course [109]. This drug's association with serotonin syndrome and its relative frequent intraoperative use should put anesthesiologists on high alert for MH-like signs. Methylene blue should be avoided in patients currently taking an SSRI.

Infection

Infection as a trigger for MH has been studied in susceptible pigs. Endotoxin injection, and the febrile state that follows, does not lead to MH. The outcome of septic, MH-susceptible pigs was worse, however, when they were also given a triggering agent. This finding is not surprising, because both stressors are potentially lethal [110]. In humans, a study of patients and their families after a suspected MH episode associated with appendicitis showed that only one of 13 were MH susceptible, but three other patients died and were assumed to be MH susceptible [111]. Death occurred in two patients despite the administration of dantrolene. No criteria could distinguish the septic patients from the patients who were MH susceptible. One study did not find any MH susceptibility by IVCT in a group of patients who developed postoperative fever [96].

Exercise and Heat Stress

Rhabdomyolysis has a multitude of etiologies and is characterized by muscle breakdown and elevation of creatine kinase. Commonly seen in cases of MH, it can also be triggered by intense exercise or heat in certain patients. Exertional heat stroke may be associated with MH, but it is not identical [90, 112]. Whether MH-susceptible patients are at increased risk of exertional heat stroke remains a

topic of controversy. Exercise-related problems are infrequently reported in MH-susceptible patients; however, a 2001 case report of exercise-related death raised cause for concern [113]. In this case a patient with a history of anesthetic-induced MH developed muscle rigidity after football practice and subsequently developed elevation in CK and lethal ventricular fibrillation. The patient, his father, and other family members were identified as harboring a typical MH-causative mutation. Although frequently associated with heat stress, several deaths have been attributed to MH after or during exercise. Underlying cardiac arrhythmias were frequently found, and these deaths could therefore be easily dismissed as related to cardiac arrhythmias. Furthermore, many patients who have a diagnosis of MH susceptibility have undergone strenuous exercise with little evidence for an unusual response. While some patients have been exposed to exercise in a controlled environment and shown no adverse effects [114], many suspicious cases have been reported [87, 88, 115]. In a study of 12 young men who developed rhabdomyolysis after exertion, nine were positive on the halothane-caffeine contracture test, and three of those displayed one of the typical MH-causative mutations [116].

In a knock-in mouse model with human RYR1 malignant hyperthermia mutations, exercise alone did not show increased rhabdomyolysis, but with an increase in ambient temperature, animals died of malignant hyperthermia [117, 118]. In a model in which homozygotes were viable, it could be shown that gene dose (homozygous vs. heterozygous), male gender, and elevated environmental temperatures increased the risk of death in MH-susceptible animals [118]. These studies further support the apparent multifactorial etiology for triggering an MH-like episode. While exercise alone could bring on rhabdomyolysis in a recent family cohort study, it was most often only triggered by a combination of stimuli, such as heat, exercise, and alcohol [94].

Since rhabdomyolysis, acidosis, and hyperthermia may be attributed to exercise or resuscitation alone, muscle rigidity and postmortem fever seem to be the major diagnostic criteria for

malignant hyperthermia-related rhabdomyolysis [119]. Muscle biopsy for caffeine halothane contracture testing should not be ordered until the patients have recovered from rhabdomyolysis (≥ 6 months), because damaged muscle may give rise to abnormal IVCTs. One may, however, send muscle tissue for molecular genetic testing.

Differential Diagnosis

Given that the signs of MH consist of tachycardia, acidosis, hypercarbia, fever, and muscle destruction, either together or in various combinations, it is not surprising that other syndromes may resemble MH (Table 5). Sepsis probably is confused most often with MH. Patients undergoing urinary tract surgery; ear, nose, and throat surgery; or appendectomy for appendicitis develop fever and sometimes acidosis. Elevated CK also may occur during episodes of sepsis. In contrast to MH, muscle rigidity is uncommon, although rigors may be mistaken for rigidity. In addition, signs of sepsis are treated effectively with nonsteroidal anti-inflammatory drugs and antibiotics. MH does not respond to such nonspecific therapy. Dantrolene often may be associated with acute reduction of fever. This finding is also nonspecific, however. Differentiating sepsis from MH is often not possible clinically.

Brain injury from a variety of causes has also been mistaken for MH [120, 121]. Patients may

Table 5 Differential diagnosis of malignant hyperthermia

Amphetamine toxicity	Intracranial bleed
Anticholinergic syndrome	Lethal catatonia
Brain injury	Meningitis
Cocaine toxicity	Neuroleptic malignant syndrome
Contrast-induced neurotoxicity	Pheochromocytoma
Drug/alcohol withdrawal	Salicylate toxicity
Extrapyramidal syndrome	Sepsis
Heatstroke	Serotonin syndrome
Hypoxic encephalopathy	Sympathomimetic toxicity
Iatrogenic overheating	Thyrototoxicosis

become febrile from hypothalamic damage or hemorrhage into the cerebral ventricles and may appear rigid due to posturing. If adequate ventilation is not provided, they may become hypercapnic. Ongoing muscle destruction is often associated with high temperatures ($\geq 42^\circ\text{C}$ [107.6°F]). Seizures can also produce an image of muscle rigidity. In contrast to MH, treatment with neuromuscular blocking agents will relax muscles and prevent acidosis, though true seizure activity requires treatment with anticonvulsants to prevent brain injury.

Endocrine disorders, such as pheochromocytoma and thyrotoxicosis, may produce increased oxygen consumption, tachycardia, hypertension, fever, and cardiovascular collapse. They have occasionally been misdiagnosed as MH. Pheochromocytoma is particularly difficult to diagnose, since patients often do not report a history suggestive of episodes of hypertension [122].

Iatrogenic overheating has been misdiagnosed as MH. In these situations, the patient is usually completely draped, the patient is externally warmed, and the procedure is lengthy. The patient develops fever, hypercarbia, tachycardia, and tachypnea if unparalyzed. Simple undraping leads to lysis of the fever, especially in an unanesthetized patient.

NMS is an idiosyncratic adverse drug reaction to neuroleptic drugs as well as to the newer atypical neuroleptics such as olanzapine and clozapine. There is no pathognomonic feature, nor are there diagnostic tests available for this syndrome. In contrast to the typically rapid onset of MH, NMS usually develops over days to weeks after initiation of the neuroleptic drug. NMS patients typically present with fever, extrapyramidal symptoms (e.g., rigidity, shuffling gait, resting tremors, dyskinesia, elevated CK), altered consciousness, and autonomic instability. In NMS, temperature is infrequently greater than 39°C . MH-susceptible individuals tolerate neuroleptics, and individuals with NMS have tolerated general anesthetics and succinylcholine. Nondepolarizing paralytics (e.g., vecuronium or cisatracurium) cause muscle flaccidity in patients with NMS but do *not* resolve the rigidity of MH. Although NMS is rare in the perioperative

setting, a thorough medication history is essential in making a diagnosis. Dantrolene has been shown to be beneficial in treating NMS [108] (see ► Chap. 31, “Neuroleptic Malignant Syndrome”).

Many other drugs have been implicated in creating an MH-like presentation. Exposure to any drugs that greatly increase dopaminergic, serotonergic, or catecholaminergic function, or produce central anticholinergic syndrome, can produce signs similar to those of malignant hyperthermia. In contrast to the hypercarbia of an MH episode, respiratory alkalosis, complicated by metabolic acidosis in severe cases, would be the norm with poisoning from sympathomimetics or amphetamines.

A well-studied example is serotonin toxicity, leading to serotonin syndrome. This is yet another drug-induced hyperthermia syndrome, in this case due to greatly increased central nervous system serotonin. Serotonin syndrome is classically produced by the combination of an SSRI with a monoamine oxidase type A inhibitor. For example, antidepressants with or without opioid analgesics, such as meperidine, dextromethorphan, or fentanyl, lithium, or drugs of abuse such as lysergic acid diethylamide or methylenedioxymethamphetamine (MDMA) have been implicated. Methylene blue has also recently been shown to induce serotonin toxicity in combination with drugs having SSRI activity due to its potent monoamine oxidase inhibitor activity [123]. Serotonin syndrome is characterized by a constellation of neuromuscular, autonomic, and central nervous system manifestations and can superficially resemble both MH and NMS. The onset is typically fast (≤ 24 h) after introduction of the offending drug dose or combination, and it typically resolves within 24–36 h. The severity of muscle rigidity, rhabdomyolysis, and hyperthermia is typically less than that seen in MH or NMS but can be life threatening nonetheless. A comprehensive medical history helps establish the diagnosis. Most cases of serotonin syndrome are self limited with discontinuation of the offending drug or drug combination and administration of sedation and cooling measures, but central serotonin antagonism with cyproheptadine or olanzapine has been successfully used in

severe cases The role of dantrolene in life-threatening serotonin toxicity is unclear, with no reduction of mortality in an animal model [124]. Dantrolene, as an adjunct to supportive therapy including cooling measures, has been associated with good outcomes in cases of MDMA intoxication complicated by hyperthermia and rhabdomyolysis (see ► Chap. 24, “Serotonin Syndrome”).

Other causes of misdiagnosis of MH include faulty temperature monitoring devices, faulty calibration of capnograph, absorption of carbon dioxide during laparoscopic procedures, underventilation of a septic patient, and a variety of causes of fever.

Although the only way to diagnose MH definitively is by means of the CHCT (caffeine halothane contracture testing) or the IVCT, the constellation of clinical signs may be helpful in determining the likelihood that a clinical event was related to MH. The clinical grading scale employs a point system based on the presence of signs of MH to score an episode. The details of the scoring system may be found elsewhere [125]. The utility of the scoring system depends on the completeness of data that are collected in a given patient. At present, the scoring system is used as a research tool only.

Management of Patients with Known Malignant Hyperthermia Susceptibility

Patients with MH susceptibility should have a preanesthetic evaluation. Safe anesthesia consists of either regional anesthesia with local anesthesia (all local anesthetics are safe) or general anesthesia using nitrous oxide and/or intravenous agents such as propofol, barbiturates, benzodiazepines, opioids, or ketamine. Intravenous sedation may be appropriate depending on the procedure and other patient comorbidities. All nondepolarizing neuromuscular blocking agents are safe. All potent inhalational agents and succinylcholine are MH triggers and must be avoided. Currently used potent inhalational anesthetics include desflurane, sevoflurane, and isoflurane. Halothane, enflurane, methoxyflurane, cyclopropane, and ether are no

longer available for clinical use in humans in the USA. Dantrolene pretreatment is *not* necessary.

Preparation of older-generation anesthesia machines (“workstations”) consisted of removing, closing, or disabling gas vaporizers, flowing 10 L/min of oxygen or air through the machine for at least 20 min, and changing the carbon dioxide absorbent. If a ventilator is to be used, the rebreathing bag should be affixed to the Y-piece and the ventilator cycled at 5–8/min during the 20 min flushing. The goal of these measures is to reduce the residual level of volatile anesthetic to <5 ppm, which is very unlikely to trigger an acute MH episode in a susceptible individual [127] and far below the concentration that can be detected by conventional anesthetic gas analyzers.

Current generation anesthetic workstations, using the method described above, require far longer times (e.g., >1 h) to achieve <5 ppm residual anesthetic [127]. The insertion of an activated charcoal filter (e.g., Vapor-Clean®) into the inspiratory limb of the breathing circuit results in prompt (e.g., <2 min) reduction of residual volatile anesthetic levels to <5 ppm; the filter is inserted following a brief (<2 min) flush of the breathing circuit with at least 10 L/min fresh oxygen flow. Because of the potential of users to unintentionally insert the filter in the expiratory limb, the manufactured product includes two filters for placement on both limbs of the breathing circuit. The manufacturer also recommends that high fresh gas flow be maintained during delivery of trigger-free general anesthesia [128–130] (link: <http://www.dynasthetics.com/Vapor-Clean/Vapor-Clean-IFU.pdf>).

Treatment

The success in controlling deaths from MH is due to early recognition of the acute syndrome and prompt treatment with dantrolene sodium intravenously (level of evidence [LoE] II-3). Dantrolene is a hydantoin derivative that inhibits calcium leak or release from the sarcoplasmic reticulum. Additional studies suggest significant inhibition of RyR1-dependent calcium influx via store-operated calcium entry, though this

inhibition does not involve a direct inhibition of store-operated calcium entry channels. It has no effect on excitation-contraction coupling in cardiac or smooth muscle. In an animal model of ventricular fibrillation, dantrolene was shown to facilitate successful defibrillation and return of spontaneous circulation; this was associated with a significant reduction of fibrillation-induced diastolic calcium leak/elevation [131]. Toxicity is limited when given over only a few days. Long-term administration may be associated with hepatotoxicity. The elimination half-life is 7–12 h.

Traditional preparations of dantrolene are poorly soluble in water – an initial treatment dose of 200 mg (=10 bottles) in a 80 kg patient requires 600 mL sterile water for injection to dissolve. Dantrolene is supplied as a lyophilized powder with 3 g of mannitol and sodium hydroxide to maintain pH of 9–10. Dantrium[®] or Revonto[®] must be mixed with 60 mL of *sterile water* and shaken vigorously. Each vial contains 20 mg of dantrolene.

In 2014, the FDA approved Ryanodex[®] (Eagle Pharmaceuticals), a nanocrystalline formulation of dantrolene sodium, for clinical use. Ryanodex[®] is

Table 6 Malignant hyperthermia treatment protocol

When MH is identified, notify surgeon/proceduralist and call for help; if in a freestanding surgery center or office, call 911. Immediately discontinue volatile anesthetic. If surgery must proceed, maintain anesthesia with intravenous agents and nondepolarizing muscle relaxants as needed. High oxygen flow should be employed to hasten reduction of inhalational agent level in the breathing circuit. If available, insert Vapor-Clean [®] filters into the breathing circuit to more rapidly reduce inhalational anesthetic levels
Hyperventilation: increase minute ventilation to ≥ 200 mL/kg/min, e.g., 20–25 breaths/min \times 8–10 mL/kg tidal volume). Mechanical ventilation is recommended because simulation has shown that switching to manual ventilation usually results in significantly decreased minute ventilation [138] (LoE III)
Dantrolene should be mixed and a dose of 2.5 mg/kg injected rapidly
Repeat as frequently as needed until the patient responds with a decrease in ET CO_2 , decreased muscle rigidity, and/or lowered heart rate. While the crisis is usually controlled with doses <10 mg/kg, large doses (>10 mg/kg) may be required for patients with persistent contractures or rigidity. If giving large doses (>10 mg/kg) without symptom resolution, consider alternative diagnoses. During this time, if the patient is decompensating or if blood gas shows base excess ≥ -8 , bicarbonate should be given, 1–2 mEq/kg
If temperature ≥ 39 °C or rapidly rising, cooling should begin using cold intravenous isotonic crystalloid, surface cooling, or intraperitoneal lavage with cool isotonic solution as appropriate [139] (LoE II-3). Stop cooling when temperature is ≤ 38 °C
In the case of cardiac arrest, potassium levels should be obtained immediately. If elevated or if hyperkalemia is suspected but quick lab results are unavailable, treatment should begin with calcium chloride, glucose, and insulin along with hyperventilation and sodium bicarbonate. Epinephrine and other β_2 -agonists may be lifesaving
Treatment of metabolic acidosis includes dantrolene and sodium bicarbonate as needed. Minute ventilation may need to be further increased to compensate for additional CO_2 released by any administered sodium bicarbonate (500 mL CO_2 gas is produced with administration of 25 mL intravenous sodium bicarbonate)
Arrhythmias should be treated with antiarrhythmics, with the exception of verapamil or diltiazem, because they may produce hyperkalemia or myocardial depression in the presence of dantrolene [140]. If a patient already taking oral verapamil or diltiazem is suspected of having an acute MH crisis, one should not hesitate to give dantrolene and should not reduce the initial treatment dose or avoid giving additional dantrolene if there are persistent signs of hypermetabolism or rigidity. One should exercise caution in the treatment of wide QRS complex rhythms with lidocaine or procainamide, as this may be a sign of hyperkalemia, and treatment with class 1 antiarrhythmics may result in asystole [141]
Arterial blood gases, electrolytes, creatine kinase, and coagulation studies should be obtained
When the initial crisis is under control, the patient should receive 1 mg/kg of dantrolene every 4–6 h or an infusion of 0.25 mg/kg/h for at least 24 h. Signs of recrudescence such as recurrent hypercarbia (not due to fighting the ventilator), rigidity not resolving with sedation, or recurrent myoglobinuria mandate re-bolusing with dantrolene in order to rapidly control hypermetabolism and prevent deterioration. Creatine kinase should be assessed every 12–24 h until stable
If myoglobinuria occurs, vigorous diuresis should be instituted with fluid administration and alkalinization. Each vial of Dantrium [®] or Revonto [®] contains 3 g of mannitol; 2.5 mg/kg of these dantrolene preparations gives the patient 0.4 g/kg of mannitol. One should carefully and frequently assess volume status in order to avoid either hypovolemia with impaired organ perfusion or fluid overload

vastly more water soluble – 250 mg of Ryanodex powder (1 bottle) is dissolved in 5 mL sterile water. Preclinical study in MH-susceptible swine demonstrated efficacy in treating acute MH triggered by halothane [126]. Ryanodex® contains very little mannitol. It is recommended that at least 10 mg/kg of dantrolene for treatment of an MH crisis in a 70 kg patient be immediately available wherever general anesthesia with potent agents or succinylcholine is used. While the great majority of anesthesia-induced MH episodes are associated with potent inhalational anesthetics, there are a small number of documented cases where succinylcholine alone was administered [133, 134]. Short-term side effects of dantrolene include muscle weakness, phlebitis, nausea, and vomiting [135]. The drug does not impair respiration except in patients with underlying muscle disease.

Any facility where general anesthesia is administered should be prepared to treat MH. Ambulatory surgery centers or offices that use MH-triggering agents must have a plan in place for transfer of care to an emergency room that focuses on clear communication and ongoing urgent treatment of the MH crisis [137]; interruption or delay of treatment with dantrolene may result in death or severe complications from fulminant MH. A treatment protocol should be readily available, such as the one available from the MHAUS (Table 6). It is beneficial to refer to a cognitive aid, be it the MHAUS treatment protocol, an available iPhone app (link: <http://www.mhaus.org/healthcare-professionals/managing-a-crisis/iphone-app>), or the Stanford Emergency Manual (link: <http://emergencymanual.stanford.edu>) [137]. Table 7 lists suggested items to be kept in a treatment cart.

Help in diagnosing and managing clinical cases of MH is available through a hotline service offered by the Malignant Hyperthermia Association of the United States (MHAUS) at no cost. Experts in MH share responsibility in answering questions regarding MH and its treatment 7 days a week, 24 h per day. The hotline number is 1-800-MH-HYPER (1-800-644-9737). Outside the USA the number is 0011-315-464-7079. Further details about MHAUS are given subsequently. More than 1500 calls are handled by the hotline each year; only about 300 are related to actual MH cases.

Table 7 Treatment cart for care of malignant hyperthermia: suggested supplies and equipment (link: <http://www.mhaus.org/faqs/stocking-an-mh-cart>)

Dantrolene, 20 mg/vial, 36 vials or Ryanodex®, 250 mg/vial, 3 vials
Sterile water for injection USP in 50 or 100 mL vials for mixing Dantrium® or Revonto®
Refrigerated 0.9% Sodium Chloride or Plasma-Lyte-A, 2–3 l
Sodium bicarbonate, 8.4%, 50 mL ampules x 5
Glucose 50%, 50 mL ampules × 2
Furosemide, 10 mg/mL, 2 vials
Calcium chloride 10%, 10 mL vials × 2
Lidocaine 1%, 10 mL, 2 vials
Amiodarone HCl intravenous, 450 mg
Regular insulin, 100 U/mL × 1
Syringes (3 mL) for blood gas and electrolyte analysis or ABG kits × 6 for point-of-care monitors. Blood collection tubes for CK, PT, PTT, fibrin-split products, electrolytes, platelets
Arterial and central venous pressure kits
Plastic bags for ice
Mini-Spike or similar transfer pin to mix water with dantrolene
Urinary dipstick for hemoglobin (for detection of myoglobin)
Esophageal or nasopharyngeal temperature probes
Rectal or bladder temperature probes
CK creatine kinase, PT prothrombin time, PTT partial thromboplastin time

Sources of Information Concerning Malignant Hyperthermia

Updated information may be obtained from the MHAUS (www.mhaus.org; PO Box 1069, Sherburne, NY 13460, USA), a not-for-profit patient advocacy organization. Formed in 1981 to provide information to practitioners and patients regarding MH, MHAUS sponsors a hotline and the North American MH Registry and produces pamphlets, a newsletter, a fax-on-demand service, and a website (www.mhaus.org), among other services. The phone number is 1-607-674-7901. The board of directors of MHAUS consists of laypersons and professionals. Support for MHAUS is from a variety of sources, but mostly from voluntary contributions. In addition, MHAUS sponsors and supports the

Neuroleptic Malignant Syndrome Information Service (www.nmsis.org) with goals similar to the goals described previously. Another useful resource is GeneTests (www.genetests.org).

Key Points in Hematologic Syndromes

1. Oxidant hemolysis, methemoglobinemia, and sulfhemoglobinemia share common etiologies and frequently coexist in the same patient.
2. Methemoglobinemia or sulfhemoglobinemia should be suspected when a cyanotic patient does not have a significantly depressed arterial P_aO_2 or when the history suggests toxic exposure to a known etiologic agent.
3. Methemoglobin impairs oxygen delivery by producing a functional anemia and by shifting the oxygen-hemoglobin dissociation curve to the left.
4. Oxygen carrying capacity can worsen, while methemoglobin fractions decrease or cyanosis improves if accompanying hemolysis produces significant decreases in hemoglobin concentrations.
5. Methylene blue enhances enzymatic reduction of methemoglobin but is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.
6. Dual-wavelength pulse oximetry is unreliable in the presence of methemoglobinemia or sulfhemoglobinemia.
7. Co-oximeters vary widely in their ability to detect, measure, and report sulfhemoglobinemia; some report sulfhemoglobin as methemoglobin.

e-mail: Steven.Curry@bannerhealth.com; aaron.kang@bannerhealth.com

8. Sulfhemoglobin cannot transport oxygen but shifts the oxygen-hemoglobin dissociation curve to the right; impaired oxygen delivery usually is not a problem unless accompanying hemolysis or methemoglobinemia is significant.
9. Methylene blue does not lower sulfhemoglobin fractions. Sulfhemoglobin persists for the life of the erythrocyte.

Common Errors in Management of Hematologic Syndromes

Failure to realize that arterial P_aO_2 is usually normal or at baseline values in patients with methemoglobinemia

Not recognizing that percent saturations reported by many blood gas machines are calculated, rather than measured, and can be reported as normal despite hemoglobinopathies such as methemoglobinemia

Forgetting to consider the total hemoglobin concentration when assessing impairment of oxygen carrying capacity from methemoglobinemia

Failure to seek evidence of hemolysis in patients with methemoglobinemia and vice versa

Failure to understand whether a specific co-oximeter being used in patient management detects or reports sulfhemoglobinemia

Not realizing that dual-wavelength pulse oximetry does not provide reliable

measurements of saturation in the presence of methemoglobinemia or sulfhemoglobinemia

Forgetting that known glucose-6-phosphate dehydrogenase deficiency is a contraindication to therapy with methylene blue

Failure to recognize that Heinz bodies cannot be seen on routine Wright's stain of blood

Three main syndromes result from erythrocytic oxidant stress. Removal of electrons from the protein portion of hemoglobin and other erythrocytic macromolecules leads to *oxidant hemolytic anemia*, characterized by Heinz bodies and bite cells. Removal of electrons from the ferrous iron in hemoglobin produces *methemoglobinemia*. Lastly, oxidation of hemoglobin's porphyrin ring by sulfur results in *sulfhemoglobinemia*. The etiology, pathophysiology, occurrence, diagnosis, and treatment of oxidant-induced hemolytic anemia, methemoglobinemia, and sulfhemoglobinemia are entangled (Fig. 1) [1–3].

Some chemical agents responsible for oxidant hemolysis, methemoglobinemia, or sulfhemoglobinemia frequently lack oxidizing potential in vitro. Their ability to produce oxidant stress is explained most commonly, however, by electrophiles produced from metabolism by cytochrome P-450 enzymes. For example, dapsone, benzocaine, and some sulfonamides are metabolized to hydroxylamines that are responsible for producing oxidant stress.

The circulating red blood cell lacks mitochondria and depends on glycolysis and the hexose monophosphate shunt for energy production (Fig. 2). Adenosine triphosphate produced in

Fig. 1 Consequences of erythrocytic oxidant stress

Fig. 2 Erythrocytic energy production. *ADP* adenosine diphosphate, *ATP* adenosine triphosphate, *G6PD* glucose-6-phosphate dehydrogenase, *GSH* reduced glutathione, *GSSG* oxidized glutathione, *NAD* nicotinamide

adenine dinucleotide, *NADH* reduced nicotinamide adenine dinucleotide, *NADP* nicotinamide adenine dinucleotide phosphate, *NADPH* reduced nicotinamide adenine dinucleotide phosphate

glycolysis meets energy requirements, whereas glycolytic production of reduced nicotinamide adenine dinucleotide (NADH) is essential in maintaining methemoglobin fractions within the normal range. The hexose monophosphate shunt produces reduced nicotinamide adenine dinucleotide phosphate (NADPH), which is used to protect against oxidant-induced hemolysis [4].

Hemolysis

Pathophysiology and Etiology

Erythrocytes constantly encounter oxidant stress from multiple sources, including food, infection, oxygen, drugs, and chemicals. Oxidation of the protein portion of hemoglobin results in denaturation and attachment of damaged protein to the internal cell membrane, which is visible as Heinz bodies with special staining of blood smears. Erythrocytes filled with denatured hemoglobin are trapped in the microcirculation of the spleen,

where pieces of plasma membrane are removed (resulting in bite cells) or where entire red blood cells undergo destruction, producing extravascular hemolysis (nonspherocytic) [3, 5]. Oxidant stress may produce hemolysis by several additional mechanisms, including depletion of intracellular glutathione stores with direct damage to the erythrocytic membrane and oxidation of other proteins, such as enzymes needed for erythrocyte integrity. Tremendous oxidant stress (e.g., chlorates) can produce intravascular hemolysis as well.

The erythrocyte protects itself from oxidant-induced hemolysis by reducing oxidants before protein denaturation occurs [4]. Reduced glutathione, nonenzymatically and enzymatically with glutathione peroxidase, is responsible for most reducing capacity in this regard. Catalase also reduces hydrogen peroxide; ascorbate is a mild reducing agent (Fig. 3).

Adequate stores of reduced glutathione are maintained within the erythrocyte through the conversion of NADPH to NADP (see Fig. 2). NADPH formation requires a properly

Fig. 3 Protection against hemolysis by reduction of oxidants. *GPX* glutathione peroxidase, *GSH* reduced glutathione, *RBC* red blood cell

functioning hexose monophosphate shunt. Patients who display congenital deficiency of glucose-6-phosphate dehydrogenase (G6PD), the first enzyme in the hexose monophosphate shunt, can be predisposed to hemolysis from sources of oxidant stress that would not affect normal phenotypes. The most common sources of oxidant stress producing hemolysis in these patients are infection, drugs, and food. Oxidant-induced hemolysis can be produced in anyone, however, if oxidant stress is severe enough, such as after overdose with numerous drugs (e.g., phenazopyridine, dapsone) (Table 1).

Logically, substances producing oxidant hemolysis share the ability to produce methemoglobinemia and sulfhemoglobinemia. Some agents are known better for producing hemolysis than accompanying dyshemoglobinemias, however. Naphthalene, an aromatic hydrocarbon, produces hemolysis [6] and less commonly is associated with severe methemoglobinemia. On the other hand, chlorates [7] produce hemolysis but also can cause marked methemoglobinemia.

Clinical Presentation and Diagnosis

Other than the expected effects of acute anemia, complications of hemolysis include hyperkalemia and pigment nephropathy. Jaundice may appear after a few days. Methemoglobinemia and occasionally sulfhemoglobinemia commonly accompany Heinz body hemolytic anemia, and evidence for this should be sought.

Hemolysis is diagnosed by showing decreases in blood hemoglobin and serum haptoglobin concentrations and a rise in plasma-free hemoglobin concentration. Hemoglobinuria results when plasma concentrations of hemoglobin increase sufficiently to saturate haptoglobin and turn plasma pink or red. In oxidant-induced disease, bite cells may be noted on routine Wright's stain of blood [3]. Heinz bodies can be detected with special staining, but they are not detectable with Wright's stain of blood. Spherocytes are typically absent or only mildly increased in number. Reticulocytosis is delayed for several days after onset of hemolysis.

Treatment

In general, treatment is supportive with blood transfusion, ensuring appropriate hydration, and monitoring for hyperkalemia. Specific therapies may be indicated with specific toxins (e.g., exchange transfusions for arsine, D-penicillamine for copper). Intravenous *N*-acetylcysteine prevented severe decreases in whole-blood glutathione concentration in cats with acetaminophen-induced methemoglobinemia [8], and in vitro studies in human erythrocytes revealed that incubation in solutions containing *N*-acetylcysteine can prevent oxidant hemolysis produced by various agents [9, 10]. No reports have shown *N*-acetylcysteine's effectiveness, however, at preventing or lessening oxidant hemolysis in humans with acute poisoning.

^aPoisoning (and sometimes therapeutic doses) by these agents variously produces combinations of Heinz body hemolytic anemia, methemoglobinemia, or sulfhemoglobinemia in individual patients. Why some patients develop methemoglobinemia, whereas others mainly develop sulfhemoglobinemia or hemolysis, is not well understood

^bKnown for producing extraordinarily severe hemolysis

^cHemolysis usually not significant after a single therapeutic dose, even when methemoglobinemia is present

Methemoglobinemia

Pathophysiology

Reduced hemoglobin (deoxyhemoglobin) contains four ferrous (Fe^{2+}) heme groups capable of binding and transporting oxygen. Oxidation to the ferric (Fe^{3+}) state produces methemoglobin. Oxidant stress produces denaturation of hemoglobin with hemolysis and methemoglobin, explaining the coexistence of both disorders in the same patient (see Fig. 1).

Reduced (ferrous) hemoglobin continuously undergoes conversion to methemoglobin within erythrocytes, to a large extent from the oxidizing power of oxygen. Values for methemoglobin are reported most commonly in percentages (fractions). These fractions represent the percentage of all hemoglobin pigments present as methemoglobin. Methemoglobin fractions in whole blood are normally less than 1–2%. When fractions exceed this value, methemoglobinemia is said to be present. Hemoglobinemia refers to the presence of excess hemoglobin in plasma, whereas methemoglobinemia refers to elevated circulating fractions of methemoglobin within erythrocytes.

Methemoglobin does not transport oxygen. Ferri heme groups impair unloading of oxygen by ferrous heme on the same hemoglobin tetramer, shifting the oxygen-hemoglobin dissociation curve to the left [4]. Serious signs and symptoms from methemoglobinemia result from impaired oxygen delivery to tissues and from cyanosis, which can be seen before significant impairment of oxygenation.

Visible cyanosis is produced by 5 g of normal deoxyhemoglobin per 1 dL of capillary blood [11]. Because methemoglobin is dark brown, however, only 1.5 g of methemoglobin per dL of blood is required to produce noticeable discoloration [12]. In nonanemic patients, about 10–15% methemoglobinemia produces cyanosis without significant impairment of oxygen delivery. Progressive increases in methemoglobin fractions to 20–40% in nonanemic patients are accompanied by headache, dyspnea, tachypnea, tachycardia, and mild hypertension. Further increases in methemoglobin fractions into the 40–55% range (without anemia) may begin to produce confusion, lethargy, and metabolic acidosis. Additional increases result in coma, seizures, bradycardia, ventricular dysrhythmias, and hypotension; near 70% methemoglobinemia results in death. We have seen one nonanemic patient who was awake with 73% methemoglobinemia after benzocaine exposure during a transesophageal echocardiogram who complained only of weakness and voices and noises sounding distant.

Anemic patients experience more severe impairment of oxygen delivery and more severe signs and symptoms at given methemoglobin fractions than nonanemic patients. Anemic patients also exhibit less profound cyanosis at given methemoglobin fractions.

Although inactivation of oxidants is the main mechanism by which oxidant hemolysis is prevented, oxidant inactivation remains relatively unimportant in maintaining methemoglobin fractions within the normal range. Patients with congenital glutathione deficiency, G6PD deficiency, catalase deficiency, and scurvy do not have elevated methemoglobin fractions. Rather, methemoglobin fractions are maintained at low levels by allowing methemoglobin to form and then immediately enzymatically reducing it back to ferrous hemoglobin.

Erythrocytic cytochrome- b_5 reductase accounts for virtually all normal methemoglobin reduction (Fig. 4) [13]. In this process, electrons from NADH (produced in glycolysis) are used to reduce cytochrome b_5 , which reduces methemoglobin to form ferrous hemoglobin. Normal enzymatic methemoglobin reduction requires an intact

Fig. 4 Mechanisms of maintaining low methemoglobin (MetHbFe³⁺) fractions through MetHbFe³⁺ reduction. Significant MetHbFe³⁺ reduction in vivo occurs only through cytochrome-*b*₅ reductase, which uses reduced nicotine adenine dinucleotide (NADH) as a reducing agent. Methylene blue markedly enhances MetHbFe³⁺ reduction by acting as a cofactor for reduced nicotine adenine dinucleotide phosphate (NADPH) MetHbFe³⁺ reductase, an

enzyme that normally plays no role in MetHbFe³⁺ reduction. Riboflavin can act like methylene blue and has been used in cases of congenital methemoglobinemia. Ascorbate and glutathione are responsible for a minority of MetHbFe³⁺ reduction in vitro but play an insignificant role in normal MetHbFe³⁺ reduction and there is limited evidence for their effectiveness in treating methemoglobinemia. HbFe²⁺, normal ferrous hemoglobin

glycolytic pathway for NADH production, the presence of cytochrome *b*₅, and adequate activity of cytochrome-*b*₅ reductase. The normal rate of enzymatic methemoglobin reduction exceeds spontaneous background methemoglobin formation rate by several 100-fold. Heterozygous erythrocytic cytochrome-*b*₅ reductase-deficient patients ordinarily exhibit normal methemoglobin fractions but are predisposed to developing methemoglobinemia in response to oxidant stress. Compound heterozygous and homozygous patients display congenital methemoglobinemia [13, 14].

A second erythrocytic reducing enzyme, NADPH methemoglobin reductase, normally remains minimally active or completely inactive because of the absence of an electron transfer intermediate (e.g., cytochrome *b*₅) to serve as a cofactor for enzymatic methemoglobin reduction. Methylene blue (methylthioninium chloride) is an acceptable electron acceptor/donor intermediate, however, and markedly accelerates NADPH methemoglobin reductase activity [4]. In this pathway (see Fig. 4), electrons are transferred from NADPH (produced in the hexose monophosphate shunt) to

methylene blue to form leukomethylene blue. Leukomethylene blue donates an electron to methemoglobin to produce ferrous hemoglobin. Reduction of methemoglobin by this pathway requires an intact hexose monophosphate shunt, a cofactor such as methylene blue, and normal activity of erythrocytic NADPH methemoglobin reductase. In vitro, some methemoglobin reduction can be shown by glutathione and ascorbate, but these are thought to be relatively minor in vivo.

The predisposition of infants to methemoglobinemia is explained by normally low erythrocytic cytochrome-*b*₅ reductase activity and cytochrome *b*₅ concentrations. Oxidant stress resulting from gastroenteritis and other infections is the most common cause of acquired methemoglobinemia in this age group [15, 16].

Etiology

Congenital Causes

Patients with compound heterozygous or homozygous deficiency for erythrocytic cytochrome-*b*₅

reductase have congenital methemoglobinemia and can be treated with oral methylene blue to lower methemoglobin fractions. In addition, several mutant hemoglobin species (hemoglobin M) in which the iron remains in the ferric form have been described. Most of these patients have congenital methemoglobinemia unresponsive to methylene blue. Rare mutant unstable hemoglobins undergo denaturation to produce congenital Heinz body hemolytic anemias; some of these also oxidize to form methemoglobin. These hemoglobins would be expected to produce disease before adulthood [5, 13].

Acquired Causes

Most cases of methemoglobinemia in adults and non-neonates are acquired, resulting from exposure to chemical agents (see Table 1). One of the most common causes is benzocaine, which is metabolized to a methemoglobin-producing agent. Methemoglobinemia resulting from topical benzocaine spray used to perform transesophageal echocardiograms, endotracheal intubations, bronchoscopies, or other endoscopic procedures has been described repeatedly in the literature [17, 18]. The use of benzocaine-containing teething ointments and hemorrhoidal creams also has produced methemoglobinemia in some patients, even after therapeutic doses. Prilocaine is the second local anesthetic most closely associated with methemoglobinemia, but methemoglobinemia has resulted from many anesthetics, including lidocaine and bupivacaine [19, 20]. Methemoglobinemia usually follows overdose of phenazopyridine (Pyridium) or dapsone and occasionally results from therapeutic use. A plethora of additional prescription drugs have been associated with methemoglobinemia; examples are valproate [21], clofazimine [22], flutamide [23], and ifosfamide [24]. Oral overdoses with nitroglycerin and organic nitrates (which are esters of nitrite) and therapeutic doses of intravenous nitroglycerin are well known to produce methemoglobinemia [25].

The conversion of nitrates to nitrites by bacteria in the upper gastrointestinal tract has produced fatal methemoglobinemia in infants who ingest well water high in nitrate concentrations –

so-called well-water methemoglobinemia [26]. Nitrite contamination of public drinking water also explained a large outbreak of methemoglobinemia [27]. Methemoglobinemia results from ingestion of meat containing excessive amounts of sodium nitrite as a preservative [28] and from the recreational use of inhalational nitrites (e.g., isobutyl nitrite). Illicit drugs can be adulterated with local anesthetics as in the case of cocaine [29]. Aniline has been sold as the hallucinogen 2C-E, with resultant methemoglobinemia [30]. Topical contact with aniline dyes found in printing ink on diapers, leather dyes in new shoes, and commercial marking crayons has produced methemoglobinemia and death [4]. The ingestion of nitroethane, found in some over-the-counter fingernail products, produces methemoglobinemia [31]. In Asia, ingestions of the herbicide propanil is a cause of methemoglobinemia [32].

As expected, most agents producing methemoglobinemia also produce oxidant-induced hemolysis, and both disorders commonly coexist in the same patient. Hemolysis can be extraordinarily severe after poisonings by chlorates, arsine, stibine, and chromates. Methemoglobinemia resulting from local anesthetics usually is not accompanied by serious hemolysis. G6PD deficiency has not been reported to predispose to methemoglobinemia except for the suggestion that hemolysis in these patients masks methemoglobinemia because older erythrocytes predisposed to increased methemoglobin formation are the very same ones more susceptible to hemolysis [33].

Diagnosis

The use of multiwavelength co-oximetry allows for the diagnosis of methemoglobinemia. It is important that the sample is analyzed soon after collection as methemoglobin concentrations can increase *ex vivo*. Modern co-oximeters measure the absorption of multiple wavelengths of ultraviolet light by blood and calculate concentrations of oxyhemoglobin, reduced hemoglobin, methemoglobin, and carboxyhemoglobin. Because co-oximetry determines methemoglobin concentrations by

measuring absorption of light, substances that interfere with light absorption can produce false results on some co-oximeters, depending on the model. Hyperlipemia, such as that seen after the infusion of lipid emulsions or in patients with diabetes mellitus, has resulted in reporting of falsely elevated methemoglobin fractions [34]. Co-oximetry may be unreliable for several minutes immediately after a dose of methylene blue [35]. As discussed later, sulfhemoglobin is handled in various ways, depending on the specific instrument, but some co-oximeters cannot differentiate between sulfhemoglobin and methemoglobin, reporting elevated methemoglobin fractions in both instances.

Other diagnostic clues commonly lead to the presumed diagnosis of methemoglobinemia before co-oximetry is considered. Generalized cyanosis in the presence of a normal arterial PO_2 usually represents methemoglobinemia. As expected, cyanosis from methemoglobinemia persists despite oxygen therapy. Patients with significant methemoglobinemia may exhibit chocolate-colored or abnormally dark blood. When methemoglobin fractions exceed 10–15% in a nonanemic patient, a drop of blood allowed to dry on filter paper appears noticeably brown compared with venous blood from a normal person [36]. In fact, the degree of color change can be used to estimate methemoglobin fraction [37]. Many blood gas instruments do not measure percent hemoglobin saturation but report a calculated value derived from the P_aO_2 and pH. This calculated saturation represents what the saturation should be in the absence of abnormal hemoglobin pigments. In methemoglobinemia, the true percent saturation as determined by co-oximetry is lower than the calculated percent saturation as reported by many blood gas instruments. The difference between the calculated and measured saturation is termed the *saturation gap* and normally is less than 3–5% in arterial blood. Large saturation gaps in arterial blood almost always result from methemoglobin or carboxyhemoglobin and less commonly result from sulfhemoglobin.

Dual-wavelength pulse oximeters, the most commonly used devices, neither accurately nor reliably measure percent saturation in the presence

of methemoglobinemia [38]. Depending on the true oxygen saturation, dual-wavelength pulse oximetry may read falsely low or falsely high. The most common response to methemoglobinemia is that pulse oximeters read falsely high saturations, although reported saturations may decrease below the normal range. When the diagnosis of methemoglobinemia has been made, the pulse oximeter should be removed from the patient so that medical personnel are not misled by unreliable readings. Over the last several years, pulse co-oximeters have become available that measure methemoglobin fractions (Masimo Corporation, Irvine, CA) and appear to provide consistent results across a wide range of hypoxia states [39]. As these devices are incorporated into regular use, methemoglobinemia may become more commonly recognized.

Blood should be drawn to screen for hemolysis (hemoglobin, blood smear, Heinz body stain, plasma-free hemoglobin, serum haptoglobin), for arterial blood gases and co-oximetry, and for routine laboratory studies. Methemoglobinemia does not change measurement of total blood hemoglobin concentration by the clinical laboratory. However, as noted earlier, it is important that a full blood count is obtained as methemoglobin concentration should be interpreted in the context of total hemoglobin. An electrocardiogram may help exclude myocardial ischemia.

Methemoglobin fractions commonly increase after death. Postmortem methemoglobin concentrations do not reliably reflect antemortem methemoglobinemia [40].

Differential Diagnosis

Arterial P_aO_2 , in the absence of other causes of hypoxemia, is normal in methemoglobinemia, distinguishing abnormal coloration from hypoxia. The cyanosis from methemoglobinemia does not respond to oxygen therapy.

Patients with sulfide poisoning have been reported to exhibit an unusual, poorly characterized discoloration of the skin and other organs, mainly as a postmortem finding. Rare cases of tellurium exposures have produced blue discoloration. Some patients with severe cyanide toxicity

exhibit cyanosis, and many other signs and symptoms of cyanide poisoning would be similar to signs and symptoms of methemoglobinemia. Normal arterial P_aO_2 and increased saturation gaps also characterize carbon monoxide poisoning and sulfhemoglobinemia, and some co-oximeters measure and report sulfhemoglobin as methemoglobin. Skin discoloration from dermal contact with new blue clothing or blue towels has been confused with methemoglobinemia, but this discoloration is removed with washing the skin. Excessive administration of methylene blue can produce skin discoloration that may be confused with continuing methemoglobinemia or cyanosis from other causes.

Treatment

Patients should receive oxygen to maximize oxygen carrying capacity of remaining normal hemoglobin.

Asymptomatic Patients

Some patients with methemoglobinemia exhibit cyanosis but lack other signs and symptoms and do not require specific treatment. After exposure to the offending agent ends, methemoglobin levels usually return to normal within 36 h with some exceptions (e.g., dapsone, nitroethane). Most of these patients require admission to the hospital, however, to follow them clinically for worsening signs and symptoms, to monitor for onset of hemolysis, and to follow serial methemoglobin fractions. Assuming normal hemoglobin concentrations, asymptomatic patients usually exhibit methemoglobin fractions between 10% and 15%.

Symptomatic Patients

Patients who are symptomatic from methemoglobinemia (e.g., tachycardia, dyspnea, confusion, and headache) should be considered for specific antidotal therapy with methylene blue [41–43] (level of evidence II-2), in the absence of a history of G6PD deficiency (see later). Parenteral methylene blue should be given intravenously over 3–5 min at an initial dose of 1–2 mg/kg

(0.1–0.2 mL/kg of a 1% solution). Resolution of cyanosis usually occurs within 5–25 min. If the patient is seriously symptomatic and no response occurs within 15 min or if the patient remains moderately symptomatic without any improvement for 30–60 min, repeat doses of 1 mg/kg (0.1 mL/kg of a 1% solution) should be given. If methemoglobin levels are readily available, repeat determinations of methemoglobin fractions should be performed before repeat dosing of methylene blue because large doses of methylene blue produce discoloration of the skin. The total amount of methylene blue given during the first few hours generally should not exceed 5–7 mg/kg. Intraosseous infusion of methylene blue has been described when intravenous access cannot be obtained [44].

Patients with methemoglobinemia always should be closely followed for evidence of hemolysis because the latter is common whether or not patients receive methylene blue. Hemolysis may be clinically apparent on presentation or, most commonly, appears 2–3 days after admission and after methemoglobin fractions have decreased.

Some toxins are known for producing methemoglobinemia that is refractory or only partially responsive to methylene blue therapy. In most instances, this situation results from the inability of methemoglobin reduction, even in the presence of methylene blue, to keep up with profound oxidant stress. Examples of these toxins include aniline, nitrobenzene, and chlorates [7, 45, 46].

Some methemoglobin-producing toxins possess long half-lives and produce prolonged methemoglobinemia. Dapsone produces methemoglobinemia and hemolysis lasting for days [47, 48]. In these cases, it may be necessary to administer methylene blue as a continuous infusion. Methylene blue is dissolved in the crystalloid of choice and, based only on case reports, started at 0.1 mg/kg/h (0.01 mL/kg/h of a 1% methylene blue solution) [47], although personal experience indicates that higher rates may be required at times. It is important to follow serial methemoglobin fractions and total hemoglobin concentrations.

Most methylene blue is excreted unchanged by the kidneys. Although patients with renal

insufficiency do not require changes in initial methylene blue doses, they should receive lower continuous infusion doses of the drug based on creatinine clearance. No specific guidelines for dosing in renal failure patients have been developed.

Methylene blue should not be given to patients with *known* G6PD deficiency. These patients have low red blood cell NADPH concentrations, impairing augmentation of NADPH methemoglobin reductase by methylene blue [49]. Methylene blue triggers hemolysis in patients with G6PD deficiency, which would impair oxygen delivery further [2, 50]. Methylene blue should never be withheld from symptomatic patients, however, simply because a history of G6PD deficiency cannot be excluded.

Large doses of methylene blue in normal volunteers have been associated with dysuria, substernal chest pain, nausea, tachycardia, hypertension, and anxiety [51]. In our experience, however, patients with methemoglobinemia do not voice or experience these effects from methylene blue. Urine initially turns blue and then green. Although authors have cautioned that methylene blue paradoxically may increase methemoglobin fractions when given in large doses (e.g., 5 mg/kg over 35–70 min) [52], this has not been thought to be a significant problem in humans receiving recommended doses. This phenomenon has been attributed largely to results of *in vitro* studies during hypoxic conditions [53, 54]. Worsening hemolysis also has been alleged after methylene blue therapy, even in patients with normal G6PD activity, but these allegations mainly arise from case reports in which hemolysis was expected from the agent producing methemoglobinemia [55], making causal relationships unclear.

Fetuses and newborns seem to be sensitive to hemolytic actions of methylene blue. Intra-amniotic injections of methylene blue, sometimes using large doses, have been associated with delivery of newborns with Heinz body hemolytic anemia. Hemolysis also has been reported in newborns receiving methylene blue through feeding tubes [56, 57]. Reports of newborns with methemoglobinemia after intra-amniotic injection of methylene blue [58] could reflect a peculiar

susceptibility of neonates, the effects of a large relative dose of methylene blue, or *in utero* hypoxic conditions favoring methylene blue-induced oxidant stress in the fetus. Regardless of these concerns, the administration of methylene blue to a symptomatic patient with methemoglobinemia has never been proved to worsen methemoglobinemia.

Cimetidine has been used to help control methemoglobinemia from dapsone. Cimetidine inhibits cytochrome P-450 conversion of dapsone to the oxidizing metabolite responsible for methemoglobinemia, dapsone hydroxylamine. In patients receiving 1,200 mg/day of cimetidine orally while taking therapeutic doses of dapsone, circulating methemoglobin fractions decreased by an average of 25% [59] (level I). However, evidence for cimetidine's effectiveness in treatment for dapsone *overdose* should be considered level III as there are no studies describing its effectiveness in this setting. Ascorbic acid works slowly and generally is considered ineffective for treatment of acute acquired methemoglobinemia [4].

Riboflavin also can accept electrons from NADPH methemoglobin reductase and enhance methemoglobin reduction in a manner similar to that of methylene blue. Although endogenous riboflavin concentrations are not high enough to account for significant methemoglobin reduction, large oral doses (e.g., 60–100 mg/day) have been used successfully in patients with congenital methemoglobinemia [60, 61]. The safety and efficacy of intravenous or oral riboflavin for the treatment of acquired acute methemoglobinemia have not been described.

Incubation of erythrocytes in high concentrations of *N*-acetylcysteine seems to enhance methemoglobin reduction [62]. These concentrations of *N*-acetylcysteine cannot be achieved safely in humans, however, and a randomized controlled trial found that conventional doses of intravenous *N*-acetylcysteine were ineffective in reducing nitrite-induced methemoglobin fractions in human volunteers [63].

It is important always to monitor total oxygen carrying capacity by following total hemoglobin concentrations, methemoglobin fractions, and true percent saturation of oxyhemoglobin. A

decrease in methemoglobin fraction from 25% to 15% would result in worsened oxygen delivery if accompanying hemolysis has resulted in a decrease of the hemoglobin concentration from 15 g/dL to 5 g/dL. In addition, the development of anemia alone may result in resolution of cyanosis despite worsening of oxygen delivery, without a decrease in methemoglobin fractions. In most persons, 15% methemoglobinemia with a hemoglobin concentration of 15 g/dL would produce visible cyanosis, whereas 20% methemoglobinemia in patients with a hemoglobin concentration of 5 g/dL produces no visible discoloration and yet may be lethal. Interpreting disappearance of cyanosis to mean that the patient has improved must be done with caution.

After initial signs and symptoms of methemoglobinemia have been addressed, routine gastrointestinal and skin decontamination should be performed as indicated. If the clinician chooses to use ascorbic acid in treating acquired methemoglobinemia, recommended doses historically have been 0.5–1 g of ascorbic acid given every 6 h intravenously or orally [4], though a recent anecdotal report describes using higher doses (described below) [64]. Evidence supporting ascorbic acid’s effectiveness in treating acquired methemoglobinemia is level III.

Failure to Respond to Methylene Blue

When patients with methemoglobinemia do not improve with methylene blue therapy, several possibilities should be considered (Table 2). First, exposure to large amounts of drugs or chemicals can produce methemoglobin at rates greater than reducing capacity, even with methylene blue therapy. When methemoglobin fractions do not return to normal because of continued methemoglobin formation, methylene blue therapy almost always results in at least a transient decrease in methemoglobin fractions. As noted earlier, recurrent methemoglobinemia is common after exposure to etiologic agents with prolonged absorption or long half-lives. Second, patients who do not respond to methylene blue also may be suffering from unrecognized G6PD deficiency. Third, patients with congenital NADPH methemoglobin

Table 2 Possible explanations when methemoglobinemia fails to respond to methylene blue

Overwhelming oxidant stress from ingestant or toxin
G6PD deficiency
NADPH methemoglobin reductase deficiency
Sulfhemoglobinemia
Blue skin discoloration from other sources
Hypoxemia (recheck arterial PO ₂)
<i>G6PD</i> glucose-6-phosphate dehydrogenase, <i>NADPH</i> reduced nicotinamide adenine dinucleotide phosphate

reductase deficiency also fail to respond to methylene blue [4]. Fourth, sulfhemoglobinemia can be mistaken for methemoglobinemia (see later). Fifth, repeated doses or large doses of methylene blue produce blue skin coloration that may be mistaken for methemoglobinemia [65].

For patients who cannot receive or fail to respond to methylene blue, treatment options are limited. Blood transfusions and exchange transfusions [46] have been used and suggested whenever refractory methemoglobin fractions approach 70% in nonanemic patients. Hyperbaric oxygen can be a temporizing measure that provides adequate oxygen delivery during preparation of blood transfusions. Oxygen toxicity limits the amount of time a patient can stay in a hyperbaric chamber, however. Oral riboflavin could be given (60–100 mg/day divided into three doses), but its efficacy is unknown in this setting, and it would not be expected to be effective in patients with G6PD deficiency. Intravenous ascorbic acid (500 mg) also can be given [4], although it is stated that it works too slowly to be helpful for acquired methemoglobinemia. High-dose ascorbic acid (10 g IV q 6 h) has been described in dapsone poisoning [64].

Sulfhemoglobin

Background and Characteristics

Sulfhemoglobin is a green molecule in which a sulfur atom has been incorporated into the porphyrin ring of hemoglobin [66]. Sulfhemoglobin cannot transport oxygen. No significant circulating sulfhemoglobin normally exists, but

sulfhemoglobin fractions increase in some persons in response to oxidant stress. In contrast to methemoglobin, sulfhemoglobin persists for the life of the erythrocyte and does not undergo conversion back to hemoglobin. Only 0.5 g/dL of sulfhemoglobin produces slate-gray cyanosis (e.g., approximately 3% sulfhemoglobin in a patient with a total hemoglobin concentration of 16 g/L).

Although sulfhemoglobin cannot transport oxygen, additional factors usually prevent serious impairment of oxygen delivery in nonanemic patients. During sulfhemoglobinemia, hemoglobin tetramers usually contain only one or two sulfurated heme isomers, preventing extremely elevated sulfhemoglobin fractions. Sulfurated heme moieties in hemoglobin shift unaffected heme moieties toward the unliganded confirmation, reducing oxygen affinity of normal heme subunits and shifting the oxygen-hemoglobin dissociation curve to the right, which enhances oxygen delivery to tissues and partially ameliorates the effects of reduced oxygen binding capacity [67]. In contrast, methemoglobin and carboxyhemoglobin shift the dissociation curve to the left, compounding impaired oxygen delivery to tissues.

Sulfhemoglobin, methemoglobin, and hemoglobin M possess similar light absorption spectra. This fact prevented many early authors from distinguishing among these three pigments. Some multiwavelength co-oximeters today report sulfhemoglobin as methemoglobin. In addition, early studies of “sulfhemoglobinemia” from hydrogen sulfide mixed with blood in vitro may have represented nothing more than a mixture of oxidized, denatured hemoglobin pigments that were unrelated to what is termed sulfhemoglobin today [68]. Readers must interpret cautiously confusing older medical literature on reports of sulfhemoglobinemia, which has been suggested to be better termed *pseudosulfhemoglobin* [69]. These articles might represent true reports of sulfhemoglobinemia, methemoglobinemia, hemoglobin M disease, various species of denatured hemoglobin from hydrogen sulfide mixed with blood in vitro, combinations of the aforementioned, or perhaps other chemical compounds.

Formation and Etiology

Agents that produce sulfhemoglobinemia (see Table 1) usually are known better for their ability to produce methemoglobinemia and hemolysis. Methemoglobinemia and sulfhemoglobinemia have followed exposures to metoclopramide [70, 71], flutamide [23, 72], dapsone [73], and phenazopyridine [74]. Methemoglobinemia, sulfhemoglobinemia, and especially hemolysis may coexist in the same patient [73]. Why exposure to the same substance produces sulfhemoglobinemia in one person, methemoglobinemia in another, and both in another person remains unknown.

Sulfhemoglobin forms when elemental sulfur binds to the β -pyrrole ring of the heme moiety, where it persists for the life of the erythrocyte [66]. Although early authors suggested that the sulfur responsible for oxidizing hemoglobin was found in the etiologic chemical, many drugs that produce sulfhemoglobinemia do not contain sulfur. It also was an older belief that vague gastrointestinal dysfunction alone produced hemolytic anemia, sulfhemoglobinemia, and methemoglobinemia from the presumed absorption of endogenously produced nitrites and sulfides – so-called enterogenous cyanosis. Evidence indicates, however, that patients with enterogenous cyanosis were ingesting surreptitiously analgesics known to cause such disorders [75].

Animal studies suggest that sulfur from intestinal bacterial metabolism in combination with oxidant stress from various agents might be responsible for sulfhemoglobin formation. Rats with jejunal pouches that received phenacetin were more likely to develop sulfhemoglobinemia than controls; neomycin prevented phenacetin-induced sulfhemoglobin formation [76]. Neomycin use for treatment of sulfhemoglobinemia in humans has been described in case reports [77].

Diagnosis

In early attempts to clarify what was being measured when “sulfhemoglobin” was reported to be present, Michel and Harris [78] reported that the

addition of cyanide or dithionite (hydrosulfite) to blood eliminated the spectral absorption of methemoglobin immediately, whereas the spectral absorption of sulfhemoglobin remained. This simple test did not exclude hemoglobin M (or perhaps other oxidation products of hemoglobin), however, which also remains after addition of these compounds. Carrico and colleagues [79] reported that carbon monoxide would bind to sulfhemoglobin to produce carbonmonoxysulfhemoglobin, a compound with a downfield shift, whereas neither methemoglobin nor hemoglobin M bound carbon monoxide. Light absorption in the presence of cyanide (or dithionite) and carbon monoxide, then, served for several years as laboratory tools to measure “sulfhemoglobin” fractions and concentrations, although it is not known confidently exactly what species always was being measured. Park and Nagel [67] reported that electrophoresis with isoelectric focusing reliably delineates the three pigments, and isoelectric focusing generally serves as the gold standard today, although various methods of analysis (e.g., gas chromatography, manual spectrophotometry) are used at reference laboratories.

Results from isoelectric focusing, manual spectrophotometric analysis, or other reference methods do not return for hours to days, whereas multiwavelength co-oximetry results are available within minutes in most intensive care units. Different brands of co-oximeters and various models from the same manufacturer vary in how they handle sulfhemoglobin [80]. The older IL 282 and IL 482 (Instrumentation Laboratory, Inc., Lexington, MA) do not distinguish between methemoglobin and sulfhemoglobin and report sulfhemoglobin as methemoglobin [71, 72, 81]. Zwart and colleagues [82] showed that a reported methemoglobin fraction greater than 10% in combination with a negative carboxyhemoglobin fraction on these instruments suggests that at least some sulfhemoglobin is present. Conversely the IL 682 is said to indicate sulfhemoglobin fractions greater than 1.5% [81]. Some multiwavelength co-oximeters will alert that sulfhemoglobin is present, but not provide quantification [83]. Wu and Kenny [84] noted that Radiometer OSM3 co-oximeter reported falsely elevated oxygen

saturations in the presence of sulfhemoglobinemia, unless the blood specimen was analyzed with a service program configuration that could be activated only by a company representative. The intensivist must be familiar with how his or her particular co-oximeter handles and reports sulfhemoglobin (if at all) and sometimes must remain skeptical of claims made by a manufacturer regarding the ability to detect and quantify sulfhemoglobin accurately.

Few data exist on accuracy of dual-wavelength pulse oximetry in the presence of sulfhemoglobinemia. We have seen one woman with slate-gray cyanosis and 18.6% sulfhemoglobin (total hemoglobin 9 g/dL) whose pulse oximeter read in the 60% range despite an elevated arterial P_{aO_2} and absent methemoglobin (true saturation about 81%). Aravindhan and Chisholm [67] described a 48-year-old woman with an arterial P_{aO_2} of 99 mmHg, 28% sulfhemoglobinemia, and a pulse oximeter reading of 85% (true saturation about 72%). Langford and Sheikh [85] noted a pulse oximeter reading of 92–94% saturation with a sulfhemoglobin fraction of 16% (true saturation about 84%).

Clinical Presentation

The diagnosis of sulfhemoglobinemia usually is considered when confronted with a cyanotic or slate-gray patient who has a normal P_{aO_2} . Depending on the co-oximeter being used, methemoglobin fractions may be reported as normal, or methemoglobin fractions may be reported as elevated and remain so after methylene blue therapy (other causes of this scenario were described previously). Except for discoloration, most patients with sulfhemoglobinemia remain asymptomatic, unless other abnormal hemoglobins are present (e.g., methemoglobin), or the typical accompanying oxidant hemolytic anemia is severe. Discoloration most often appears slate gray and lasts for weeks or months due to the irreversible nature of sulfhemoglobin [12]. The coexistence of methemoglobinemia and anemia may alter the color of cyanosis and clinical symptoms.

Historically the most common drugs causing sulfhemoglobinemia were acetanilid, phenacetin, and sulfonamides. Bromo-Seltzer was the most common cause, but acetanilid, the offending ingredient, since has been removed as an ingredient. More recent reports describe sulfhemoglobinemia resulting from dapsone [73], dimethyl sulfoxide [86], flutamide [72], metoclopramide [71], and phenazopyridine [74].

Treatment

There is no specific antidote for sulfhemoglobinemia. No beneficial effect results from therapy with methylene blue. Treatment centers on ensuring adequate oxygen delivery to tissues by correcting coexistent methemoglobinemia and anemia (from hemolysis) and ensuring maximal oxygen carrying capacity with administration of oxygen when the patient is symptomatic. Transfusions usually are required only in patients whose coexisting hemolytic anemia is severe, which increases the total hemoglobin concentration and decreases the sulfhemoglobin fraction. Patients need follow-up on an outpatient basis for several weeks because sulfhemoglobin concentrations decrease only as the red blood cell population is replaced in the absence of the offending agent.

Neuroleptic malignant syndrome (NMS) is an uncommon but potentially fatal idiosyncratic complication of antipsychotic drug therapy. It was first described in 1960 when Delay and colleagues [1] reported rigidity and fever associated with haloperidol therapy. The syndrome subsequently was named and classified as a drug-induced extrapyramidal syndrome (EPS) by Delay and Deniker in 1968 [2]. The term *neuroleptic malignant syndrome* is derived from the French *syndrome malin des neuroleptiques* [3]. Although now infrequently fatal and not always associated with antipsychotic therapy, NMS remains the preferred term to describe this illness.

NMS is a heterogeneous disorder with a wide spectrum of clinical severity [4, 5]. It is commonly characterized by the tetrad of altered consciousness, fever, muscular rigidity, and autonomic dysfunction [6]. NMS has been reported with nearly all antipsychotic drugs [7]. It also has been reported with other drugs that antagonize dopaminergic neurotransmission in the central nervous system (CNS) (e.g., amoxapine, metoclopramide, lithium) and in patients with Parkinson's disease who abruptly discontinue dopamine agonist therapy [5, 8–20]. Many drugs that are not known to antagonize dopamine neurotransmission rarely have been implicated as etiologic agents for NMS (Table 1) [21–42]. These drugs produce movement disorders, muscular rigidity, and fever by a mechanism different from that of NMS and are better characterized as producing NMS-like syndromes rather than true NMS.

Table 1 Agents reported to cause neuroleptic malignant syndrome

Antipsychotic agents	Non-antipsychotic agents
Typical agents	Agents that deplete dopamine
Butyrophenone	α -Methylparatyrosine [10]
Droperidol	Reserpine
Haloperidol	Tetrabenazine [10, 21]
Dihydroindolone	
Molindone	Antiepileptics
Diphenylbutylpiperidine	Carbamazepine [22, 23] ^a
Pimozide	Phenytoin [24] ^a
Phenothiazine	Valproic acid [38] ^a
Aliphatic	Lamotrigine [39]
Chlorpromazine	
Promethazine	Cyclic antidepressants
Piperazine	Amitriptyline [21, 25] ^a
Fluphenazine	Desipramine [26] ^a
Perphenazine	Dothiepin [27, 28] ^a
Prochlorperazine	Imipramine [30] ^a
Trifluoperazine	Maprotiline [31] ^a
Piperidine	Trimipramine [32] ^a
Mesoridazine	
Thioridazine	Selective serotonin reuptake inhibitors:
Thioxanthene	Fluoxetine [29, 40] ^a
Chlorprothixene	Paroxetine [40] ^a
Clopenithiol	
Flupenthixol	Dopamine receptor antagonists
Thiothixene	Amoxapine [17, 18]
Zuclopenthixol	Metoclopramide [14–16]
Atypical agents	Miscellaneous agents
7-[4-[4-(2,3-dichlorophenyl)-1-piperazinyl]butoxy]-3,4-dihydrocarbostyryl	Cocaine [33] ^a
	Estrogen [42] ^a
Aripiprazole	Monoamine oxidase inhibitors
Benzamides	Phenelzine [25, 35] ^a
Raclopride	
Remoxipride	Psychotropic agents
Sulpiride	Lithium [17, 20]
Sultopride	
Benzisothiazol piperazine	Skeletal muscle relaxants
Ziprasidone	Cyclobenzaprine [36] ^a
Benzisoxazole	Diazepam [37] ^a
Risperidone	Lorazepam [21] ^a
Paliperidone	

(continued)

Table 1 (continued)

Antipsychotic agents	Non-antipsychotic agents
Dibenzodiazepine	Withdrawal of dopamine agonists
Clozapine	Amantadine [9, 10, 12]
Dibenzo-oxepino pyrrole	Bromocriptine [9–11]
Asenapine	Levodopa/carbidopa [11, 13]
Dibenzothiazepine	
Quetiapine	
Dibenzoxazepine	
Loxapine	
Thienobenzodiazepine	
Olanzapine ^a	

^aAlthough these agents have been reported to cause neuroleptic malignant syndrome (NMS), evidence consists of one or two case reports for each agent, and the reported cases often have coingestants that may produce muscular rigidity and fever. For each case, the syndrome reported should be characterized as an NMS-like syndrome rather than true NMS

To date, more than 1,000 cases of NMS have been reported in the literature, largely as individual case reports, case series, and reviews [4, 5, 21, 41–44]. Collectively, these cases have heightened awareness of NMS, facilitated its early recognition, promoted a reduction of suspected risk factors, and allowed more timely treatment. As a result, the incidence and mortality from NMS have decreased since the 1980s [5, 7, 44–47]. However, the lack of animal models and controlled, prospective treatment studies for NMS has hampered a full understanding of its pathophysiology and optimal treatment. Further study is necessary to reduce the incidence, morbidity, and mortality from NMS.

Epidemiology

Incidence

NMS is uncommon. From retrospective studies, reported incidences have ranged from 0.02% to 3.2% of individuals exposed to neuroleptic drugs [6, 43, 50]. In four prospective studies, incidences ranged from 0.02% to 2.2% [47–49, 50a]. In one

prospective study, Keck documented four cases in 2,695 patients treated with antipsychotics from 1986 until 1990 [47]. The agents implicated for each patient were fluphenazine (patient 1); fluphenazine, chlorpromazine, amantadine, and lithium (patient 2); perphenazine (patient 3); and chlorpromazine, perphenazine, and fluoxetine (patient 4). Gelenberg et al. note a single case in 1,470 treated patients in 1 year, from 1986 to 1987 [49]. The patient developed NMS during treatment with haloperidol and amitriptyline. In a study by Spivak et al., there described 19 cases among 78,708 treated patients over a 10-year period from 1986 to 1995; 84.2% of patients that developed NMS were treated with haloperidol [48]. Estimates of frequency are influenced by diagnostic criteria, patient populations studied, prevalence of risk factors, setting, and methods of data collection [6]. If NMS were recognized across a spectrum of severity and widened diagnostic criteria were employed to diagnose it, the prevalence of this disorder would be higher. When data are pooled from many studies, NMS is estimated to occur in 2 of every 1,000 patients treated with antipsychotics [6].

Demographics

NMS occurs in all age groups. Most cases occur in patients between 20 and 50 years old with a mean age of 40 [5–7, 43]. This age distribution likely reflects the pattern of antipsychotic drug use in society rather than a true age predilection for the disease [5, 6]. NMS occurs approximately twice as often in men compared with women [5–7]. This occurrence also likely reflects the pattern of neuroleptic use, with a higher frequency of use in men.

Risk Factors

Several potential risk factors for the development of NMS have been identified from case series and reviews. These include rapid initiation of antipsychotic therapy; use of high-potency agents and/or depot preparations; dehydration; severe agitation or catatonia; requirement of restraints or

seclusion; preexisting organic brain disease, mental retardation, or affective disorder; previous treatment with electroconvulsive therapy (ECT); previous history of NMS; poorly controlled EPS; and concomitant use of predisposing drugs, such as lithium, anticholinergic agents, and anti-Parkinson agents [5–7, 43, 45]. In two similarly designed case-control studies in which 43 patients with NMS were compared with 75 matched neuroleptic-treated controls, risk factors were better delineated [51, 52]. NMS was more likely to occur in patients who had been agitated, been dehydrated, required restraint or seclusion, received a larger number of intramuscular injections, and received larger doses of neuroleptic agents soon after hospital admission (rapid dose titration).

NMS has been associated with all antipsychotic agents. Most cases have been reported, however, with high-potency agents and depot preparations. NMS also has been reported with atypical antipsychotics, but it is not yet known whether its incidence is lower with use of these newer agents. In one review of 115 cases of NMS, 57% were attributed to haloperidol, 16% to fluphenazine, and 17% to a depot preparation [5]. The higher frequency of NMS associated with higher-potency antipsychotic agents may reflect their more frequent prescribing pattern or rates of administration, however, and not a true increased risk. In this same review, the low-potency agent chlorpromazine was implicated in 24% of cases of NMS; its overrepresentation in NMS cases probably reflects its frequent use at the time of the study [5]. Whether the incidence of NMS is truly higher with depot preparations is not clear either. In this same NMS case review, the depot preparation fluphenazine decanoate was implicated in 16% of cases compared with 5% for patients treated with oral fluphenazine. In contrast, oral haloperidol was implicated in 57% of NMS cases compared with 1% for its depot preparation [5].

NMS is idiosyncratic. Its occurrence is not correlated with dose, and it usually occurs with antipsychotic serum concentrations in the therapeutic range [5–7, 43, 45]. Although NMS may occur at any time during therapy, it usually

appears in the first 1–2 weeks of treatment or soon after a change in dosage [5–7, 43]. The rate of increase of neuroleptic dose correlates with the likelihood of developing NMS [43, 51]. The decline in the incidence of NMS may reflect an appreciation of this risk factor and a significant decline in “rapid tranquilization” of agitated psychiatric patients [47, 49, 50].

NMS occurs independent of race, geographic location, environmental temperature, and humidity [5–7]. There is no seasonal variation in incidence [6]. Although there have been rare reports of NMS occurring within the same family, there does not seem to be any significant genetic predisposition to its occurrence [5–7, 53]. Although individuals with preexisting affective and organic brain disorders are at greater risk for developing NMS, the illness occurs across the neuropsychiatric disease spectrum and occurs in patients without organic and functional brain disorders as well [5–7, 51, 54].

Pathophysiology

Although the pathophysiology of NMS is not fully understood, it primarily involves dopaminergic hypoactivity in the CNS [6–8, 55, 56]. Several lines of clinical evidence support this theory. First, all antipsychotic agents have been associated with NMS, and all share the ability to bind and antagonize D₂-dopamine receptors [55, 57, 58]. Second, other agents that block D₂-receptors (e.g., amoxapine, metoclopramide) or result in depletion of dopamine (e.g., reserpine, α -methylparatyrosine, tetrabenazine) have been reported to produce NMS [5, 8, 10, 14–18, 59]. Third, the abrupt discontinuation of dopamine agonists (e.g., amantadine, levodopa/carbidopa) in patients with Parkinson's disease has been reported to produce a syndrome identical to NMS [8–13]. Fourth, treatment with dopamine agonists (e.g., bromocriptine, amantadine) improves the signs and symptoms of NMS [5, 6, 43, 44, 60–65]. Fifth, if dopamine agonist therapy is withdrawn prematurely from patients with NMS who have been treated, signs and symptoms may return [65]. Sixth, a significant reduction of the dopamine metabolite homovanillic acid has

been observed in the cerebrospinal fluid of some patients with NMS compared with control subjects [66].

Functionally, the signs and symptoms of NMS largely can be explained by medication-induced blockade of D₂-dopamine receptors in the hypothalamus, striatum, mesocortical and mesolimbic areas, peripheral sympathetic nerve terminals, and vasculature [8, 55, 67]. Neuroleptic blockade of D₂ receptors in the nigrostriatum may produce muscle rigidity and parkinsonism [55, 67]. Neuroleptic blockade of D₂ receptors in the thermoregulatory center (preoptic area) of the anterior hypothalamus may produce hyperthermia [55, 67]. Injection of dopamine into the preoptic area of the hypothalamus of animals results in hypothermia, and this effect can be blocked by haloperidol [68]. Intraventricular injection of the dopamine receptor antagonist chlorpromazine causes a rise in core temperature [69]. The fever of NMS is the result of increased heat production from muscle rigidity, impaired heat dissipation, and possibly a higher set-point of core temperature in the hypothalamus. Drug-induced blockade of mesocortical and mesolimbic D₂ pathways partly mediates the altered mentation of NMS [55]. Neuroleptic antagonism of dopamine receptors present on peripheral sympathetic nerve terminals and vascular smooth muscle cells may mediate the autonomic dysfunction associated with NMS [70]. Antagonism of presynaptic D₂ autoreceptors increases the release of norepinephrine, whereas antagonism of postsynaptic D₂ receptors results in vascular relaxation in select areas [71]. Supersensitivity of these receptors that results from repeated dopamine antagonist administration contributes to autonomic irregularity. Clinically, tachycardia, hypertension, blood pressure lability, diaphoresis, pallor, tachypnea, and incontinence may result.

The time delay between the administration of antipsychotic drugs and the occurrence of NMS suggests that factors other than acute effects of drug itself are operative in the initiation of the syndrome. Centrally, nigrostriatal and mesolimbic regions have presynaptic D₂ autoreceptors, which diminish the release of dopamine when stimulated [71]. Peripherally, sympathetic ganglia and

postganglionic sympathetic nerve terminals have presynaptic D₂ autoreceptors, which diminish the release of norepinephrine when stimulated [72]. Exposure to antipsychotic agents may initiate the development of supersensitivity at the presynaptic and the postsynaptic dopamine receptors. Autoreceptors are more sensitive to dopamine, however, than are postsynaptic receptors and are affected to a greater degree [71]. Supersensitivity at the presynaptic area results in decreased dopamine output and contributes to dopaminergic hypoactivity. Although supersensitivity of postsynaptic receptors occurs with repeated neuroleptic administration, the acute administration of rapidly escalating doses predominantly results in postsynaptic depolarization blockade [71, 73]. When postsynaptic blockade is coupled with presynaptic downregulation (decreased dopamine production and release), marked dopaminergic hypoactivity results, and patients are at risk for NMS. Why NMS occurs in such a small minority of patients treated with neuroleptics is unknown.

NMS and EPS (e.g., acute dystonia, parkinsonism, akathisia) are closely related entities, both of which result from neuroleptic blockade of nigrostriatal D₂ receptors [55, 57, 67, 73]. NMS is often considered a severe form of EPS with fever that has progressed from unrecognized or inadequately treated milder forms of EPS [4, 5, 7, 54, 74, 75]. Despite its similarity to EPS, however, NMS has a unique pathophysiology that probably reflects complicated, time-dependent neuroreceptor effects yet to be elucidated. Anticholinergic agents are not efficacious for the treatment of NMS but are highly effective for acute dystonia and parkinsonism. Time-dependent changes in neuroreceptor function may be responsible for a lack of response to these agents in the setting of NMS.

The pathophysiology of NMS may involve iron. Iron is a positive modulator of dopamine receptor activity. Low serum iron levels often are found in patients with NMS and may lead to a decreased expression of dopamine receptors in the brain [76, 77]. It is not known whether low serum iron levels are a primary cause of NMS or occur as a result of the illness. Low serum iron may simply

reflect a nonspecific acute phase response in certain patients with NMS [78].

Although dopaminergic blockade is central to the pathobiology of NMS, the alterations of other neurotransmitter systems are likely important as well. Neuroleptics may modulate the activity of a variety of other neurochemicals (e.g., γ -aminobutyric acid [GABA], acetylcholine, norepinephrine, serotonin, glutamate, aspartate, enkephalin, dynorphin, substance P, somatostatin, cholecystokinin, neurotensin, vasoactive intestinal peptide, and various prostaglandins) through specific receptor binding or indirectly as a result of altered dopamine neurotransmission [8, 56]. Imbalance between dopaminergic activity and one or more of these neurochemicals may mediate the signs and symptoms of NMS. The interactions are complex, varied throughout the CNS, and not well understood. In addition to striatal D₂-receptor antagonism, the muscular rigidity and akinesia associated with NMS result from alterations in levels of substance P, dynorphin, enkephalin, glutamate, and GABA in various basal ganglial pathways [8, 56].

One provocative theory suggests that NMS results from disinhibition of glutamatergic and other excitatory amino acid pathways in the CNS [56, 79]. Normally, excitatory amino acid activity in corticostriatal and subthalamic pathways is antagonized by nigrostriatal dopaminergic neurons. Blockade of dopamine receptors by antipsychotic drugs disinhibits the *N*-methyl-D-aspartate (NMDA) glutamate receptor, resulting in an excess of glutamatergic neurotransmission and the rigidity of NMS [56, 79]. There is evidence to support this theory. Amantadine, an NMDA-receptor antagonist, ameliorates the rigidity of NMS and induces hypothermia in animals [56, 80]. GABA-receptor agonists (e.g., benzodiazepines) inhibit glutamate neurotransmission and are helpful in the treatment of NMS [5, 8, 56].

Direct skeletal muscle effects from neuroleptics may mediate partly the rigidity, fever, and serum elevations of creatine kinase associated with NMS. In vitro, neuroleptics have been shown to inhibit calmodulin, increase ionized calcium, and result in skeletal muscle fiber contraction; this action may be inhibited by dantrolene

[81–83]. A primary peripheral cause of NMS is unlikely, however, because dantrolene sometimes is ineffective for the treatment of this syndrome [5, 21, 44, 84].

Clinical Features

NMS is most commonly characterized by fever, muscular rigidity, altered mental status, and autonomic dysfunction [5, 6]. Fever and muscular rigidity usually are present but are not required for diagnosis. NMS is a heterogeneous syndrome that occurs across a spectrum of severity [4]. Signs and symptoms vary and are influenced by the timing of diagnosis and treatment. Fever (temperature $\geq 38^\circ\text{C}$ [100.4°F]) occurs in 79–100% of patients, and temperatures exceed 40°C in approximately 40% of patients [5, 6, 21, 42–44]. Muscular rigidity is present in 92–97% of patients and is usually parkinsonian or “lead pipe” in nature [5, 6, 8, 43, 44, 85]. The rigidity of NMS typically is unresponsive to anticholinergic treatment [5, 6]. Mental status alteration is reported in 97% of cases and may range from mild inattentiveness, lethargy, and confusion to severe unresponsive catatonia, stupor, and coma [5, 6, 8, 44, 85]. Agitation and delirium also have been described. Autonomic dysfunction has been reported in 100% of patients and includes fever, tachycardia, tachypnea, hypertension or hypotension, blood pressure lability, diaphoresis, sialorrhea, pallor, flushing, urinary incontinence, and cardiac dysrhythmias [5–7, 43, 44, 85].

Extrapyramidal movement disorders frequently are present in patients with NMS and include tremor, bradykinesia, akinesia, hypomimia, festinating gait, chorea, dystonias (e.g., opisthotonos, trismus, blepharospasm, buccofacial dyskinesia, and oculogyric crisis), nystagmus, opsoclonus, dysphagia, dysarthria, and aphonia [5–7, 44, 85]. These findings are expected if one accepts NMS as an extreme form of EPS. Other neurologic abnormalities include akinetic mutism, hyperreflexia, extensor plantar responses, ataxia, abnormal flexor or extensor posturing, ocular flutter, impaired upward gaze, and seizures [5–7, 43, 44, 85].

Clinical Course

Although NMS may occur at any time during neuroleptic therapy, most cases (66–89%) occur within 2 weeks of drug initiation, dose increase, or change to a different agent [5, 6, 43, 44]. NMS peaks within 72 hours of symptom onset in most patients (79–90%) [5, 6, 43, 44]. In one review of 115 cases of NMS, however, it took 4–30 days for 18 (21%) patients to evolve into the full syndrome [5]. When neuroleptics are stopped, signs and symptoms of NMS resolve within 1–61 days [5, 6, 43, 44]. In one study of 65 patients not treated with dantrolene or dopamine agonists, the mean duration of NMS was 9.6 ± 9.1 days [84]. The duration of illness is not different in pediatric patients [44]. The clinical course is nearly twice as long, however, for patients who have received intramuscular depot preparations [5, 6, 43]. In one study of 115 patients, the mean duration of NMS was 13 days for non-depot neuroleptics and 26 days for depot agents [5].

Most cases of NMS seem to follow a sequence of development. Mental status changes or muscular rigidity precedes autonomic dysfunction and hyperthermia in 82.3% of cases [74]. These findings support the theory that psychomotor agitation and muscular rigidity contribute to the development of fever. Early recognition of confusion, catatonia, or worsening EPS may facilitate prompt treatment and halt progression to a fulminant syndrome [54, 74].

Laboratory Findings

Although laboratory abnormalities frequently are present with NMS, none are specific to or pathognomonic for NMS. Elevation of serum creatine phosphokinase (CPK) (greater than three times normal) is the most frequent laboratory abnormality, present in 97% of patients [5, 6]. Current, consensus-based, expert opinion states that elevations of CPK of at least four times the upper limit of normal are commonly seen in patients with NMS and this degree of elevation is used to support diagnosis [86]. Elevation of CPK reflects myonecrosis and often is associated with

rhabdomyolysis, myoglobinuria, and acute renal failure from acute tubular necrosis. Myonecrosis results from muscular rigidity, fever, and psychomotor agitation. Leukocytosis (white blood cell count 10,000–40,000/mm³), with or without a left shift, is present in 70–98% of patients [5–7, 43, 44]. Other laboratory abnormalities that may occur include hypernatremia or hyponatremia, mild elevations of hepatic aminotransferases, and low serum iron [5–7]. Patients with NMS may develop anion gap metabolic acidosis (due to increased lactic acid), hypoxemia, and elevations of creatinine and coagulation parameters [5–7, 43].

For patients with NMS, results of lumbar puncture, radionuclide brain scans, and computed tomography and magnetic resonance imaging of the head are usually normal or show nonspecific abnormalities [5–7, 43]. Electroencephalograms are normal or suggest nonspecific encephalopathy [5]. In one review of 45 patients with NMS who had electroencephalograms, 21 (47%) had nonspecific slowing, and 20 (44%) had normal studies [5]. Electromyograms and muscle biopsy specimens are normal or show nonspecific changes [5–7, 43]. Postmortem histopathologic examinations of the brain do not reveal specific structural abnormalities associated with NMS [6, 7].

Complications and Mortality

Medical complications from NMS are more likely to occur in patients with a higher severity of illness (e.g., longer duration, higher fever) or preexisting comorbid conditions (e.g., organic brain syndrome, mental retardation) [5–7, 21, 42, 43]. Rhabdomyolysis is the most frequent complication [5, 6]. Other complications include renal failure, aspiration pneumonia, pulmonary edema, pulmonary embolism, respiratory failure, sepsis, coagulopathy, disseminated intravascular coagulation, sepsis, seizures, myocardial infarction, peripheral neuropathy, periarticular ossification, necrotizing enterocolitis, cardiac arrhythmias, and cardiorespiratory arrest [5–8].

NMS initially was characterized as “malignant” because of its fatal outcome in a significant

percentage of patients. Before 1986 the mortality rates ranged from 17% to 28%, whereas since 1986 they have ranged from 0% to 11.6% [5–8, 42–47, 87, 88]. In one review of 77 cases of NMS in adolescents and children from 1966 to 1998, mortality and serious sequelae rates were 9% and 20%, respectively [44]. As in adults, the mortality rate has declined since the mid-1980s; no fatalities in children have been reported in the over 20 cases published since 1986 [44]. Mortality is correlated closely with the severity of hyperthermia. In one review of 374 patients with NMS, survival was 100% for patients with peak temperature <38 °C, 88% for patients with peak temperature between 39.0 and 39.9 °C, but only 44% for patients with peak temperature >42 °C [42]. The duration of hyperthermia is also associated with the incidence of secondary complications and lethality. In one retrospective review from Australia, first generation antipsychotics were associated with a higher mortality as compared to second generation antipsychotics [89]. In all patients with NMS, death is usually secondary to respiratory failure (e.g., aspiration pneumonia, hypoventilation), cardiovascular collapse, myoglobinuric renal failure, arrhythmias, thromboembolism (e.g., pulmonary embolism), and disseminated intravascular coagulation [5–7, 43]. In one case series, renal failure was associated with a 56% mortality rate [46]. Most adult patients who recover from NMS recover fully and do not manifest persistent neurologic sequelae [5–7].

Diagnosis

Confirmatory laboratory tests do not exist for NMS, and diagnosis is based on history, suggestive physical findings, and a high level of suspicion in the appropriate clinical setting. It is unclear whether NMS is a qualitatively distinct entity with all-or-none clinical expression or an extrapyramidal complication that occurs at the end of a spectrum of neuroleptic-induced side effects. Some investigators believe that the diagnosis should not be made unless all four classic features (i.e., fever, muscular rigidity, altered mentation, and autonomic dysfunction) are present [6, 90, 91].

Other investigators believe that NMS is a heterogeneous disorder that may be diagnosed in its milder, atypical, and incipient forms [4, 5, 54, 74, 75]. To date, a lack of uniform diagnostic criteria in the literature has produced inconsistencies in diagnosis [92]. Adoption of a single set of standardized but flexible criteria to assist diagnosis is important to advance understanding of NMS and to differentiate it from other illnesses. The use of rigid diagnostic criteria may

unnecessarily delay diagnosis and treatment, whereas flexible criteria may reduce morbidity by ensuring earlier recognition and prompt intervention [4, 54, 74, 75, 92]. Sets of clinical criteria that seem to allow for some flexibility in diagnosis are presented in Table 2 [93, 94]. Recent exposure to a dopamine antagonist, or withdrawal of a dopamine agonist, and the presence of fever and muscle rigidity are typically required to make the diagnosis of NMS. Unlike DSM-IV that identifies

Table 2 Three sets of diagnostic criteria for neuroleptic malignant syndrome

Caroff et al. [93]	American Psychiatric Association DSM-IV criteria [94]	Gurrera et al. [95] consensus-based expert criteria
1. Treatment with neuroleptics within 7 days of illness onset (2–4 weeks for depot agents)	A. Development of muscle rigidity and fever associated with the use of neuroleptics	1. Exposure to dopamine antagonist, or dopamine agonist withdrawal, within the past 72 h
2. Hyperthermia (>38 °C)	B. ≥Two of the following:	2. Hyperthermia (>100.4 °F or >38.0 °C on at least 2 occasions, measured orally)
3. Muscle rigidity	Change in level of consciousness	3. Rigidity
4. Five of the following:	Mutism	4. Mental status alteration (reduced or fluctuating level of consciousness)
Change in mental status	Tachycardia	5. Creatine kinase elevation (at least four times the upper limit of normal)
Tachycardia	Hypertension or labile blood pressure	6. Sympathetic nervous system lability, defined as at least 2 of the following:
Hypertension or hypotension		Blood pressure elevation (systolic or diastolic ≥25% above baseline)
Tachypnea or hypoxia	Diaphoresis	Blood pressure fluctuation (≥20 mmHg diastolic change or ≥25 mmHg systolic change within 24 h)
Diaphoresis or sialorrhea	Dysphagia	Diaphoresis
Dysarthria or dysphagia	Tremor	Urinary incontinence
Tremor	Incontinence	7. Hypermetabolism, defined as heart-rate increase (≥25% above baseline) and respiratory-rate increase (≥50% above baseline)
Incontinence	Leukocytosis	8. Negative workup for infectious, toxic, metabolic, or neurologic causes
Increased CPK or myoglobinuria	Laboratory evidence of muscle injury (e.g., elevated CPK)	
Leukocytosis		
Metabolic acidosis	C. Symptoms in A and B are not due to another substance or to a neurologic or general medical condition	
	D. Symptoms in A and B are not better accounted for by a mental disorder	
5. Exclusion of other drug-induced, systemic, or neuropsychiatric illness		

criteria for diagnosis (see Table 2), DSM-V describes common NMS features [86]. In a review by Gurrera et al., criteria for diagnosis of NMS was adjudicated by consensus of an expert panel [95].

Differential Diagnosis

The diagnosis of NMS should be considered whenever a patient develops fever and muscular rigidity while taking neuroleptics. Early signs of NMS also may include an unexpected deterioration of mental status, new catatonia, and the development of EPS refractory to anticholinergic therapy [54, 74]. Because NMS is an uncommon syndrome, however, the diagnosis should not be made before other causes have been considered and ruled out. Patients initially suspected of having NMS often have other medical disorders that account for their signs and symptoms [4, 96]. Recently, an NMDA-receptor encephalitis associated with ovarian or testicular teratomas has been described that has features (i.e., delirium, hyperthermia, seizures, autonomic instability, and abnormal movements) similar to NMS. Therefore, consideration to serum and cerebrospinal fluid (more sensitive) testing for anti-NMDA-receptor antibodies should be considered [97, 98]. Alternative conditions that should be part of the differential diagnosis of NMS are listed in Table 3.

One disorder that is difficult to differentiate from NMS is lethal catatonia. Lethal catatonia is a rapidly progressive, idiopathic psychiatric syndrome that is characterized by catalepsy, rigidity, waxy flexibility, stupor, mutism, fever, autonomic instability, and death [6–8, 99]. In contrast to NMS, lethal catatonia begins with extreme agitation that, if unchecked, leads to exhaustion and mutism; rigidity is a late finding. Neuroleptics are ineffective in lethal catatonia [99]. Withdrawal of neuroleptics is recommended when either NMS or lethal catatonia is suspected [99].

With the widespread use of pro-serotonergic agents, serotonin syndrome [SS] (see ► Chap. 24, “Serotonin Syndrome”) is an important part of the differential diagnosis of any drug-induced hyperthermia. Similar to NMS, SS is a clinical

Table 3 Differential diagnosis of neuroleptic malignant syndrome

Toxin-mediated alternative diagnoses
Anticholinergic agents
Central hallucinogens (e.g., ketamine, LSD, MDMA, MDEA, PCP)
Cyclic antidepressants
Drug-induced parkinsonism (e.g., amoxapine, carbon monoxide, carbon disulfide, cyanide, disulfiram, ethylene glycol, methanol, metoclopramide, MPTP, neuroleptics)
Drug interactions (e.g., monoamine oxidase inhibitor tyramine reaction, serotonin syndrome)
Drug withdrawal states (e.g., sedative-hypnotics, barbiturates, benzodiazepines, ethanol; baclofen; dopamine agonists)
Heavy metals (e.g., manganese, mercury, lead)
Lithium
Monoamine oxidase inhibitors
Salicylates
Serotonin syndrome
Strychnine
Sympathomimetics (e.g., amphetamines, cocaine, designer drugs, methylxanthines)
Non-toxin-mediated alternative diagnoses
Cerebrovascular accident (e.g., hemorrhagic stroke)
CNS tumors
Endocrinopathies (e.g., pheochromocytoma, thyrotoxicosis)
Heatstroke
Infections (e.g., brain abscess, CNS HIV infection, meningoencephalitis, postinfectious encephalomyelitis, pneumonia, sepsis, rabies, tetanus)
Malignant hyperthermia
NMDA-receptor encephalitis
Seizures
Stiff-man syndrome
Systemic lupus erythematosus
Trauma

CNS central nervous system, *HIV* human immunodeficiency virus, *LSD* lysergic acid diethylamide, *MDEA* 3,4-methylenedioxyamphetamine, *MDMA* 3,4-methylenedioxymethamphetamine, *MPTP* 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, *PCP* phenylcyclohexyl piperidine (phencyclidine)

syndrome characterized by mental status alterations, muscular rigidity, autonomic instability, hyperthermia, and serum CPK elevations. Although agent exposure history is critical for syndrome differentiation, the rate of onset and time to peak illness severity and physical exam

findings can greatly assist diagnosis. SS is characterized by (1) signs and symptoms that develop and peak over hours [rather than days with NMS] and (2) muscular rigidity that is defined by hyperreflexia and clonus [unlike lead pipe rigidity with NMS] [100].

Although NMS and malignant hyperthermia (see ► Chap. 29, “Malignant Hyperthermia”) have similar clinical characteristics, they are differentiated easily on the basis of history, clinical setting, and rapidity of onset. The two illnesses are distinct clinical entities with different pathophysiology. Malignant hyperthermia is a rare genetically transmitted abnormality of skeletal muscle calcium metabolism. After exposure to certain anesthetic agents (e.g., succinylcholine, halothane) or stress, enhanced release and impaired reuptake of calcium occur from muscle cell sarcoplasmic reticulum. Excessive excitation-contraction coupling and a syndrome of muscle rigidity and fever that may appear clinically similar to NMS result. In contrast to NMS, however, malignant hyperthermia has a genetic predisposition, it is associated with general anesthesia and not neuroleptic therapy, it is characterized by rapid onset and high mortality, and its rigidity does not respond to nondepolarizing paralytic agents [5–8, 90]. In addition, muscle fibers from patients with malignant hyperthermia have positive in vitro contraction responses to caffeine and halothane, whereas muscle fibers from patients with NMS do not contract [101].

Evaluation

The history should include the duration of neuroleptic treatment; identity, dosing pattern, and route of administration of the neuroleptic; concurrent medications; identity of any preexisting illness and NMS risk factors; and time of onset, nature, sequence, and progression of signs and symptoms. The ingestion of other substances should be documented. The initial physical examination should include a detailed assessment of vital signs, cardiopulmonary status, and neurologic function. There are no bioassays that can confirm

the diagnosis of NMS. Laboratory and adjunctive diagnostic tests are used primarily to exclude alternative diagnoses and complications [6, 7]. Typical laboratory evaluation may include a complete blood count; blood cultures; measurement of serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, magnesium, CPK, thyroid-stimulating hormone, and iron; a toxicologic screen of blood or urine or both; a urinalysis; and an electrocardiogram. Pregnancy testing is suggested for women of childbearing age. NMDA-receptor antibodies should be tested for if there is any clinical suspicion of NMDA-receptor encephalitis. There is no known direct effect of NMS on pregnancy or the fetus. Sicker patients also require measurements of coagulation parameters, liver function tests, arterial blood gas analysis, and a chest radiograph. Quantitative serum concentrations of concurrent medications (e.g., lithium) should be obtained. Other studies that may be necessary to exclude alternative diagnoses include a lumbar puncture, electroencephalogram, and computed tomography or magnetic resonance imaging of the head. Serial evaluations of vital signs, neurologic function, and serum CPK are important to determine the course of the illness and the need for further testing and intervention.

Treatment

Prevention is the most important aspect of treatment [54]. Risk factors (e.g., dehydration, agitation) should be identified and modified when possible, and neuroleptics should be discontinued in instances in which the incipient phase of NMS (e.g., severe EPS) is suspected. Management of suspected or established cases of NMS requires immediate withdrawal of neuroleptics and NMS-potentiating drugs (e.g., anticholinergics, lithium), exclusion of other medical conditions that may simulate NMS, and aggressive supportive care. The role of adjunctive pharmacotherapies is less well established. Supportive care includes provision of adequate ventilation and oxygenation; rehydration; temperature reduction; nutritional support; low-dose heparin to prevent

thromboembolic disease; and treatment of metabolic, renal, and cardiopulmonary complications [7]. Because NMS is an idiosyncratic complication that results from therapeutic dosing of neuroleptics, gastrointestinal decontamination is not indicated if the diagnosis of NMS is secure. Empirical antibiotic administration is recommended because of the initial difficulty in differentiating NMS from systemic infection. Prophylactic intubation should be considered for patients with excessive sialorrhea, swallowing dysfunction, coma, significant hypoxemia and acidosis, and rigidity with severe hyperthermia. Rehydration should be aggressive and rapid to achieve a minimum urine output of 50–100 mL/h (1 mL/kg/h) to avoid renal failure (level of evidence [LoE] III).

The effectiveness of specific treatments for NMS remains unclear; no individual therapy or combination of therapies has been shown to be universally effective or clearly superior to supportive care alone [5–7, 54, 58]. Evidence to support efficacy of individual agents is not based on controlled, prospective studies but largely on inferences from retrospective data and case reports. Selection bias, variation in the onset and severity of NMS, lack of standardized drug-dosing protocols, multiple simultaneous treatments, and the self-limited course of NMS make it difficult to establish the relative efficacy of any specific therapy compared with supportive care alone [5–7, 54, 58]. The possibility of a prospective, controlled study is unlikely because of the low incidence of NMS. Specific treatment measures that have been suggested include dantrolene, nondepolarizing neuromuscular paralysis, benzodiazepines, bromocriptine, amantadine, levodopa/carbidopa, nifedipine, nitroprusside, and ECT. All of these measures have been reported effective anecdotally in the management of NMS (LoE III).

Most evidence does not support the use of anticholinergic agents for the treatment of NMS. Anticholinergic agents do not decrease the incidence of NMS when coadministered with neuroleptics, and they are usually ineffective at reducing clinical effects or shortening the duration of illness for established cases of NMS [5, 6, 8,

43, 81]. Anticholinergics may worsen hyperthermia by impairing heat dissipation. In one retrospective review of NMS in children and adolescents, however, anticholinergic therapy was associated with a shorter duration of illness [44].

Dantrolene, a hydantoin derivative, inhibits ionized calcium release from the sarcoplasmic reticulum (see ► Chap. 142, “Dantrolene” for a discussion of its clinical pharmacology). It causes direct muscle relaxation by uncoupling excitation-contraction in skeletal muscle. It is used mainly to treat NMS-associated hyperthermia and rigidity. By reducing tonic contraction of skeletal muscles, dantrolene reduces thermogenesis and CPK release. It is given orally or by intravenous infusion. Initially, dantrolene should be administered at doses of 1–2.5 mg/kg every 6 h [5–8, 90]. Doses of up to 10 mg/kg/day are considered safe [5–8, 90]. Dantrolene should be continued until the signs and symptoms of NMS resolve, typically after 5–10 days of therapy [8, 28, 102] (LoE III). On resolution of clinical manifestations of NMS, some authorities recommend that dantrolene be tapered over 3–10 days to avoid syndrome recrudescence [50, 71, 102] (LoE III). Dantrolene may produce a variety of adverse effects, including muscle weakness, lethargy, nausea, vomiting, diarrhea, and urinary incontinence. Hepatotoxicity and seizures may occur with doses >10 mg/kg/day and when treatment extends beyond 60 days [6]. In one review of 534 cases of NMS, a positive response was noted in 84% of 44 patients treated with dantrolene alone [42].

Bromocriptine, amantadine, carbidopa-levodopa, and levodopa alone are dopamine agonists that are given to overcome neuroleptic-induced dopaminergic blockade. Dopamine agonists are given alone or in conjunction with dantrolene or other muscle relaxants. Bromocriptine, a dopamine receptor agonist, initially is administered in doses of 2.5–10 mg three to four times daily [5–7, 88]. Doses of 20 mg four times daily have been used [5–8, 44]. The appropriate dosing in children is not well established [44]. Bromocriptine is administered until the signs and symptoms of NMS resolve, typically after 5–10 days of therapy [8, 28, 102]. Duration

of treatment has ranged from 2 to 56 days [62, 64, 71] (LoE for bromocriptine use: III). Abrupt discontinuation of bromocriptine has resulted in recrudescence of the signs and symptoms of NMS [65, 71]. As with dantrolene, it is recommended that bromocriptine be tapered over 3–10 days on symptom resolution [54, 75, 102].

Amantadine, which enhances presynaptic dopamine release, is given orally two times daily (100–200 mg/dose) [6, 43, 90]. The therapeutic actions of amantadine also are mediated by its noncompetitive antagonism at the NMDA-glutamate receptor [56, 79, 80] (LoE for amantadine use: III). Sinemet, which increases presynaptic dopamine stores, is given orally three to four times daily (25/250–75/300 mg dose) [43, 85, 103]. In one review of 536 cases of NMS, bromocriptine was administered alone to 42 patients and was effective for 88% [42]. In this same review, amantadine and levodopa each were used in 16 cases; amantadine was effective in all, and levodopa was effective for 94% of patients [42]. These patients were treated concurrently with other pharmacotherapies, however, and the independent effects of amantadine and levodopa alone are unclear. In one study of adolescents and children with NMS, bromocriptine and levodopa were associated with a significantly shorter duration of illness [44]. In some cases of NMS, premature discontinuation of bromocriptine treatment has resulted in relapse of the syndrome; subsequent reinitiation of the drug has been effective [8, 65, 71].

Studies that have examined the efficacy of dantrolene and dopamine agonists have been largely retrospective. In one retrospective analysis of 67 cases of NMS, dantrolene or bromocriptine reduced the time to clinical improvement and resolution compared with supportive care alone [88]. Mean response time to clinical improvement was 1.0 day for bromocriptine, 1.7 days for dantrolene, and 6.8 days for supportive care alone. Mean time to complete resolution was 9.0 days for dantrolene, 9.8 days for bromocriptine, and 15.8 days for supportive care alone. A prospective, open, nonrandomized study of 20 patients with NMS showed a more prolonged illness and greater complication rates with

bromocriptine or dantrolene treatment, however, compared with supportive care alone [104]. The mean duration of illness was 9.9 days for patients treated with bromocriptine or dantrolene versus 6.8 days for patients treated supportively. The treatment groups in this study had a higher incidence of underlying medical illness, which may have biased results. In retrospective analyses, dopamine agonists have been reported to reduce NMS mortality rates significantly from 21% to 9.2% [105, 106]. When used alone, bromocriptine reduces mortality to 7.8% and amantadine reduces mortality to <6% [105, 106]. The combination of dantrolene with bromocriptine does not offer additional survival advantage over either drug alone [105].

Benzodiazepines have shown efficacy as adjunctive therapy for NMS [107–111]. Benzodiazepines not only decrease neuromuscular agitation in a nonspecific manner but also inhibit glutamatergic neurotransmission as GABA-receptor agonists [5, 8, 10, 43, 81, 107, 111]. Administration of benzodiazepines early in the course of illness may diminish psychomotor agitation and muscular rigidity and halt progression to the fulminant hyperthermic syndrome. Benzodiazepines also may hasten recovery from NMS [110, 111]. In one retrospective study of 16 patients with NMS, clinical improvement was noted within 24–72 hours of benzodiazepine treatment initiation (e.g., lorazepam) [111]; this compares favorably with the rates of recovery reported with other pharmacotherapies and with supportive care alone [5, 6, 111]. Initial intravenous doses of diazepam (0.1–0.2 mg/kg) or lorazepam (0.05–0.1 mg/kg) may be repeated at 10- to 30-min intervals until the desirable effect is achieved or CNS or respiratory depression occurs (LoE for benzodiazepine use: III). Although experience is limited, phenobarbital (5–10 mg/kg intravenously) may be used if psychomotor agitation is resistant to repeated benzodiazepine therapy (LoE for phenobarbital use: III).

ECT has been an effective treatment for NMS [5–8, 21, 42, 112, 113]. The beneficial effects are believed to result from an increased turnover of dopamine in the brain and increased receptor sensitivity to dopamine after ECT [114]. In one

review of 29 cases of NMS treated with ECT, a positive response was noted in 83% of patients [115]. Some investigators suggest that the incidence of mortality for NMS patients treated with ECT is lower than for patients treated supportively [115]. Cardiac arrhythmias, cerebral edema, and death have occurred after ECT in a few patients, however [6]. ECT may be reserved more appropriately for patients who fail to respond to standard pharmacotherapies or have refractory catatonia (LoE for ECT use: III).

Prompt reduction of NMS-associated muscle rigidity and hyperthermia can be expected to minimize the risk of rhabdomyolysis, renal failure, pneumonia, respiratory failure, disseminated intravascular coagulation, and cardiovascular collapse. These complications are responsible for most NMS-associated deaths, making their prevention paramount [5–7, 21, 42–44, 81, 90]. The severity of hyperthermia is correlated closely with the likelihood of death in patients with NMS [42, 44]. Although hypothalamic thermoregulatory dysfunction may have a causal role in NMS-associated fever, thermogenesis ultimately is due to tonic skeletal muscle contraction [5–8, 81, 84, 90]. Rapid muscle relaxation is the goal in patients who are severely ill (LoE III). Bromocriptine and dantrolene often take 1 or more days to reduce fever and rigidity in patients with NMS [88]. In select instances, when patients are extremely rigid and have temperatures that exceed 40 °C, it makes intuitive sense to use nondepolarizing neuromuscular paralysis (e.g., pancuronium) to achieve the most rapid, predictable, and effective reduction of rigidity and fever. Pancuronium has been used successfully to control rigidity and fever rapidly in two case reports; one of the patients had failed dantrolene therapy [84, 116]. A reasonable first approach to manage the rigidity and fever associated with NMS includes intravenous benzodiazepines (diazepam, 0.1–0.4 mg/kg, or lorazepam, 0.05–0.1 mg/kg), antipyretics, evaporative cooling, ice packs, cooled intravenous fluids, and dopamine agonist therapy (e.g., bromocriptine). Adjunctive dantrolene therapy may be beneficial as well. If rigidity persists and patient temperature exceeds 40 °C, timely neuromuscular paralysis is

recommended. Immediate paralysis also is recommended for patients who have severe hyperthermia and rigidity on initial presentation.

The sequence, type, and rapidity of intervention depend on the time course and severity of illness. In general, all patients suspected of having NMS should be admitted initially to an intensive care unit for aggressive supportive care. In 2007, Strawn et al. adapted a treatment algorithm from Woodbury and Woodbury to recommend treatments based on severity [112, 113]. For mild NMS, they recommend benzodiazepines. For moderate NMS, they recommend benzodiazepines along with either bromocriptine or amantadine. For severe NMS, they do not support the use of benzodiazepines but rather recommend dantrolene and dopamine agonist therapy (i.e., bromocriptine or amantadine). ECT may be considered as adjunctive therapy for those with moderate and severe forms of NMS [112, 113]. When the appropriate disposition or management of a patient is in question, consultation with a medical toxicologist is recommended.

To date, evidence suggests that patients with a history of NMS have a significantly greater risk for syndrome recurrence when an antipsychotic agent is reintroduced. In one review of 47 patients in whom antipsychotic drugs were reintroduced, 14 (30%) developed recurrent episodes of NMS [87]. The risk is greater when high-potency (greater D₂-receptor binding affinity) and long-acting (depot) agents are reintroduced. Of 21 patients, ten (48%) developed a recurrent episode when rechallenged with a high-potency agent compared with four (15%) of 26 patients rechallenged with a low-potency agent [87]. When reinitiation of neuroleptic therapy is necessary to treat severe psychotic illness in a patient with a history of NMS, steps should be taken to minimize the risk of syndrome recurrence. Potential risk factors, such as patient agitation and dehydration, should be minimized. The risk of recurrence is reduced significantly (8% versus 86% recurrence rate) if reintroduction of neuroleptic therapy is delayed by at least 2 weeks from an initial NMS episode [81, 117, 118]. When neuroleptics are reinitiated, low-potency or atypical agents (e.g., clozapine) should be used. In addition, low doses should be

used initially, dose titration should be gradual, and patients should be monitored closely for incipient signs of NMS [5, 6, 8, 43, 81].

Key Points in Neuroleptic Malignant Syndrome

1. When NMS is first suspected, neuroleptic agents should be discontinued immediately.
2. The diagnosis of NMS should be considered whenever a patient develops fever and muscular rigidity while taking neuroleptics.
3. The diagnosis of NMS should not be made before other medical conditions have been considered and ruled out.
4. Timely and aggressive supportive care is the most important aspect of treatment.
5. Prompt reduction of muscle rigidity and fever minimizes medical complications and optimizes survival.
6. Because NMS is a life-threatening medical emergency, all patients suspected of having the illness should be managed initially in an intensive care unit.

The first known reference to rhabdomyolysis is said to be in the Bible in the Book of Numbers, [1] in which an illness is described that occurred in Israelites after eating hemlock-fed quail. Rhabdomyolysis is a potentially life-threatening syndrome that can develop from a variety of causes. The term “Rhabdomyolysis” literally translates to “dissolution of striped [skeletal] muscle.” It is the final common pathway of a number of different processes, all of which end in skeletal muscle injury. An elevated plasma creatinine kinase (CK) level is the most sensitive laboratory finding pertaining to muscle injury; whereas hyperkalemia, acute kidney injury, and compartment syndrome represent the major life-threatening complications [2]. The clinical and biochemical syndrome of rhabdomyolysis occurs when skeletal muscle cell disruption causes release of muscle cell contents (CK, lactate dehydrogenase, aldolase, myoglobin, purines, potassium, and phosphates) into the interstitial space and plasma. Although direct mechanical trauma, compression, excessive muscle activity, and ischemia are frequent causes, direct xenobiotic-induced rhabdomyolysis results from toxic insult to the cell membrane, affecting its ability to maintain ion gradients. Although rhabdomyolysis does not indicate irreversible necrosis of muscle, life-threatening illness and multi-organ insufficiency may result [3, 4].

Most cases of rhabdomyolysis in adults are multifactorial, but those related to poisoning are generally due to one of the three clinical scenarios.

The first includes patients that develop a xenobiotic-induced sympathomimetic or hyperadrenergic state that may include seizures and/or psychomotor agitation. Second are patients with significant decreased levels of consciousness who develop muscle injury from unrelieved pressure on gravity-dependent body parts and prolonged immobilization. There are unique drugs or toxins that cause rhabdomyolysis due to direct toxicity. Examples of these unique causes include ethanol, doxylamine [5] intoxication, use of lipid-lowering agents, and ingestions of the mushroom *Tricholoma equestre* [6].

Pathophysiology

Although there are a large number of drugs or toxins that can cause rhabdomyolysis, the pathogenesis appears to follow a final common pathway, ultimately leading to myocyte destruction and release of muscle components into the circulation. In the normal myocyte, the sarcolemma has a thin membrane that encloses striated muscle fibers and contains numerous pumps that regulate cellular electrochemical gradients. The intercellular sodium concentration is normally maintained at 10 mEq/L by a sodium-potassium adenosine triphosphatase (Na/K-ATPase) pump located in the sarcolemma [7]. The Na/K-ATPase pump actively promotes sodium efflux from the cell causing the interior of the cell to be electro-negative. This electrochemical gradient result causes calcium efflux via the sodium/calcium exchange. Moreover, low cytosolic calcium levels are also maintained by an active calcium exchanger (Ca²⁺ ATPase pump) that promotes calcium entry into the sarcoplasmic reticulum and mitochondria [8]. The above processes are energy dependent.

Adenosine triphosphate (ATP) depletion, which appears to be the end result of most causes of rhabdomyolysis, results in Na/K-ATPase and Ca²⁺ ATPase pump dysfunction resulting in an increase in cellular permeability. Sodium, chloride, and water movement into the cell then is due to either plasma membrane disruption or reduced ATP production [3, 4, 9–11].

Accumulation of sodium in the cytoplasm leads to an increase in intracellular calcium concentration (which is normally very low relative to the extracellular concentration). This excess calcium then increases the activity of intracellular proteolytic enzymes that degrade the muscle cell. As the myocyte degenerates, large quantities of potassium, aldolase, phosphate, urate, creatinine kinase, lactate dehydrogenase, aspartate transaminase, and myoglobin leak into the circulation [7, 9, 10].

When myoglobin is released from myocytes, it becomes protein bound (50% at serum concentrations < 23 mg/dL) and is rapidly metabolized to bilirubin [12]. Under physiological conditions, the plasma concentration of myoglobin is very low (0–0.003 mg/dL). Free myoglobin is rapidly filtered by renal glomeruli, with an elimination half-life of 1–3 h and disappearance from the circulation within 6 h of release [13, 14]. However, if more than 100 g of skeletal muscle is damaged, the circulating myoglobin levels exceed the protein-binding capacity of the plasma and can precipitate in the glomerular filtrate [2]. Myoglobin may be released in sudden, massive amounts making it detectable before creatinine kinase [15] (Fig. 1).

Drug-Induced Rhabdomyolysis

Examples of drugs, toxins, or other agents that are associated with rhabdomyolysis are listed in Table 1 [16]. Toxicant-induced agitation, seizures, withdrawal, and hyperthermia are typical underlying features leading to rhabdomyolysis. Even in the absence of coma or seizures, ethanol ingestion (especially binge drinking) can cause muscle damage and rhabdomyolysis by an unknown mechanism [17]. However, it has been theorized that altered muscle ion homeostasis occurs because of changes in sodium-potassium transport pump activity allowing increased sodium entry into the cell [18, 19]. Nutritional deficiencies, hypophosphatemia, and hypokalemia may be coexistent risk factors for the development of rhabdomyolysis [3, 20, 21]. Cholesterol-lowering drugs of the statin class are also associated with

Fig. 1 Pathophysiology of rhabdomyolysis-induced acute kidney injury. *CO* carbon monoxide, *EC* extracellular, Fe^{2+} ferrous iron, Fe^{3+} ferric iron, Fe^4O , ferryl iron, *HO-1* heme oxygenase-1, H_2O_2 hydrogen peroxide, *MB* myoglobin, *MC* muscle cell, *MT* mitochondria, *NO* nitric oxide, OH^-

drug-induced rhabdomyolysis in the absence of other major clinical manifestations of toxicity [22]. Other unique and classic causes of rhabdomyolysis include doxylamine [5] intoxication and ingestion of the mushroom *Tricholoma equestre* [Saviuc].

Statins

Statin-associated rhabdomyolysis is rare but a well-known adverse effect of this class of drugs. Statin-induced myotoxicity is dose dependent. The concept of a dose-dependent increased risk

Table 1 Drugs and toxins associated with rhabdomyolysis[16]

Class	Examples
H2 antagonists	Famotidine, cimetidine
Analgesics and anti-inflammatory agents	Salicylates, acetaminophen, propoxyphene, opiates, buprenorphine, ibuprofen, diclofenac, phenylbutazone, sulfasalazine, glucocorticoids, pethidine, colchicine
Anesthetics	Inhalation anesthetics, propofol, ketamine, glutethimide
Antibiotics, antifungals, and antivirals	Chloroquine, hydroxychloroquine, daptomycin, fluoroquinolones, trimethoprim/sulfamethoxazole, amphotericin B, itraconazole, isoniazid, zidovudine, ritonavir, didanosine
Antidepressants, antipsychotics, and mood stabilizers	All classes antidepressants, haloperidol, risperidone, thioridazine, loxapine, amoxapine, lithium, chlorpromazine
Antihistamines and antimuscarinics	Doxylamine, diphenhydramine, all antimuscarinics
Beta-adrenergic antagonists	Oxprenolol, labetalol
Cholesterol lowering	Fibrates, HMG-CoAse reductase inhibitors (statins)
Chemotherapeutic and immunosuppressant medications	Vincristine, cytarabine, mitoxantrone, arsenic trioxide, cyclosporine A, alpha interferon, interleukin 2, azathioprine, tacrolimus, trabectedin, leflunomide
Alcohols and recreational drugs	Ethanol, ethylene glycol, methanol, heroin, methadone, cocaine, amphetamines, LSD, ecstasy, marijuana, PCP, synthetic cathinones
Sedatives/hypnotics	Diazepam, temazepam, lorazepam, chloral hydrate, barbiturates
Miscellaneous	Amiodarone, D-penicillamine, vitamin A, vitamin B6, insulin, nifedipine, phenytoin, valproate, tryptophan, laxatives, diuretics, streptokinase, aminocaproic acid, caffeine, theophylline, terbutaline, vasopressin
Toxins and environmental	Hemlock, hemlock herbs from quail, wild mushrooms (<i>Amanita phalloides</i> , <i>Tricholoma equestre</i>), snake venoms, Hymenoptera, giant desert centipede, black widow spider, toluene, carbon monoxide, hyperthermia, hypothermia, thujone containing plants (<i>Artemisia absinthium</i> [wormwood], <i>Salvia officinalis</i> [sage], <i>Tanacetum vulgare</i> [tansy], <i>Achillea millefolium</i> [yarrow], <i>Thuja plicata</i> [red cedar], and <i>Thuja occidentalis</i> [white cedar]), seafood poisoning (Haff disease due to freshwater fish, buffalo fish, crayfish, Atlantic salmon, pomfret; palytoxin due to marine reef fish, bottom feeding fish, crabs, anemones)
Tyrosine kinase inhibitors	Sunitinib, imatinib, erlotinib (when combined with simvastatin)

of statin-related muscular adverse effects is supported by the results of a meta-analysis. Overall, the observed excess of rhabdomyolysis was 4 per 10,000 patients with more intensive versus less intensive statin therapy compared with 1 per 10,000 patients on standard statin regimens versus control (at least 2 years follow-up) [23]. Although the exact mechanism of statin-associated myopathy is unclear, there appears to be vulnerability related to gene polymorphism in addition to several intracellular mechanisms. Functional variation of the hepatic uptake transporter SLCO1B1 has been implicated in statin-induced myopathy. An analysis by Carr et al. revealed the SLCO1B1 c.521 T > C single-nucleotide polymorphism to be a significant risk factor for severe myopathy

[24]. Meta-analysis showed an association between c.521C > T and simvastatin-induced myopathy, although power for other statins was limited in their study. Pathophysiologically, statins appear to deplete geranylgeranyl pyrophosphate, thereby reducing prenylated Rab. Intracellular vesicle traffic is consequently suppressed inviting mitochondrial dysfunction and ATP depletion [23, 25]. Studies have also suggested that variation in the coenzyme Q2 (COQ2) homologue gene may predispose individuals to statin-induced myopathy. In addition, abnormal mitochondrial respiratory function is caused by statin-induced coenzyme Q10 deficiency [43]. Puccetti et al. demonstrated an association between both rosuvastatin- and

atorvastatin-induced myopathy and the rs4693075 polymorphism in the COQ2 gene [26]. An association of another COQ2 variant (rs4693570) and statin-induced myalgia has also been described [27].

Some concomitant medications appear to increase the risk of statin-associated myopathy. Among the 601 cases of statin-associated rhabdomyolysis investigated by Omar et al. [28], the most common concomitant medications were mibefradil (99 patients) fibrates (80 patients), ciclosporin (51 patients), macrolide antibiotics (42 patients), warfarin (33 patients), digoxin (26 patients), and azole antifungals (12 patients).

Doxylamine

Rhabdomyolysis in uncomplicated antihistamine overdoses is uncommon. Severe cases of rhabdomyolysis following antihistamine exposures typically are associated with the development of seizures and hyperthermia [29–31]. Doxylamine, an over-the-counter drug used primarily as a sleep-inducing agent, however, is associated with rhabdomyolysis in the absence of prolonged sedation, agitation, or delirium or seizures [32]. Early studies reported that the incidence of rhabdomyolysis following doxylamine was relatively low [33]. In contrast, in urban emergency departments in Korea, doxylamine overdose accounts for 25% of visits due to drug overdose [34] and the incidence of rhabdomyolysis ranges from 32% to 77% [5, 35, 36]. In addition, rhabdomyolysis developed in 21.0% (35/169) of patients who had creatinine kinase levels within the reference range at presentation [32].

The mechanism for rhabdomyolysis in doxylamine overdose is uncertain. In the multivariate regression analysis, by Kim et al., the amount of doxylamine ingested and the initial heart rate were reliable associative factors for the development of rhabdomyolysis [Kim]. In a prospective study by Jo et al., looking at doxylamine overdose, their bivariate analysis in patients who developed rhabdomyolysis differed from those

who did not in the amount of doxylamine ingested (36.2 vs. 17.2 mg/kg, p 0.003). Initial value of serum Cr (1.3 vs. 0.8 mg/dL, p 0.022) was significantly higher and the arterial pH (7.36 vs. 7.43, p 0.032) was significantly lower in patients with rhabdomyolysis than those without [5]. In their study rhabdomyolysis was common, occurring in 87% of patients who ingested more than 20 mg/kg.

Tricholoma (equestre/flavovirens)

Several cases of massive rhabdomyolysis have been reported since 1993 in France and 2001 in Poland after ingestion of large amounts of an edible and, until then, valuable species of mushroom called *Tricholoma equestre* (common name “Man on Horseback”). Several of these cases of rhabdomyolysis were associated with respiratory complications and myocarditis leading to death [6]. The toxic dose or underlying predisposing factors for susceptibility in humans are unknown. *Tricholoma equestre* toxicity appears to require extremely large doses, in the order of 100–400 g at each meal over repeated meals [37]. The myotoxic component of *Tricholoma equestre* has not been identified. The mushroom contains triterpenoids, a high steroid and aldehyde content, indoles, and acetylenic compounds [38]. The onset is 24–72 h after the last meal, with presenting symptoms of muscle weakness, fatigue, anorexia, and muscle pain in lower extremities, progressing over several days, followed by dark urine.

Water Hemlock

Rhabdomyolysis is common in water hemlock poisoning. Patients often complain of muscle pain and tenderness at the time of presentation. It is likely to occur in patients with recurrent seizures but has also been seen in patients in the absence of seizures, although to a lesser degree. In the absence of seizures, the mechanism of myotoxicity is unknown [39–41].

Cocaine

Cocaine use leads to rhabdomyolysis through psychomotor agitation, seizures, and impaired behavioral responses [42, 43]. Serum CK values have been reported up to 100,000 U/L (1700 *ukat*/L). In large doses, cocaine has direct toxic effects on skeletal muscle causing myofibrillar degeneration. In addition, muscle ischemia from vasoconstriction may predispose to further muscle injury. Although crack cocaine is the most reported in the literature, all forms of cocaine use can cause rhabdomyolysis. A prospective case series of patients presenting to an emergency department with complaints related to cocaine use showed a high incidence of cocaine-associated rhabdomyolysis. Of all cocaine users, 24% had rhabdomyolysis, defined by an elevation of creatinine kinase of more than fivefold that of the mean level (>1000 U/L; 17 *ukat*/L). The same study found that only 13% of the patients presenting with rhabdomyolysis experienced any of the classic signs or symptoms (nausea, vomiting, myalgias, muscle swelling and tenderness, weakness) [44].

Patients at highest risk for complications from rhabdomyolysis are patients presenting with signs of sympathomimetic toxicity. A retrospective study showed that patients with acute cocaine intoxication who had admission serum creatinine kinase levels < 1000 U/L (<17 *ukat*/L), a normal serum creatinine concentration, a normal WBC, and no more than one additional risk factor for rhabdomyolysis (i.e., muscular activity, other mind-altering drugs, seizures) were unlikely to develop rhabdomyolysis [45].

Propofol

Propofol is widely used as a short-acting anesthetic and for sedation of critical ill patients. Current recommendations suggest a dosage less than 8 mg/kg/h and application not longer than 2 days in adults [46–48]. Rhabdomyolysis occurs most frequently with high doses of propofol after 96 h of administration [49]. On a molecular level, propofol is toxic for mitochondria and elevates

malonyl-carnitine concentrations [50]. It uncouples oxidative phosphorylation and inhibits the respiratory chain at complexes II and IV [51–53]. In particular, fatty acid transport is inhibited by elevated malonyl-carnitine levels that impair entry of long-chain acylcarnitine esters into the mitochondria and failure of the mitochondrial respiratory chain at complex II [53].

Rhabdomyolysis may accompany propofol infusion syndrome, a rare but extremely dangerous complication of propofol administration. Certain risk factors for the development of propofol infusion syndrome are described, most notably propofol doses and durations of administration. Based on the data from case reports and case series, it is not recommended to administer propofol for more than 48 h or infusions more than 4 mg/kg/h (67 mcg/kg/min). Other potential risk factors for the development are critical illness (sepsis, head trauma, status epilepticus, etc.), use of vasopressors and glucocorticosteroids, carbohydrate depletion (liver disease, starvation, or malnutrition), carnitine deficiency, and subclinical mitochondrial disease [54]. The syndrome commonly presents as an otherwise unexplained high anion gap metabolic acidosis (due to elevation in lactic acid), rhabdomyolysis, hyperkalemia, acute kidney injury, elevated liver enzymes, and cardiac dysfunction [54].

Clinical and Laboratory Manifestations

An elevated serum CK is the most sensitive and reliable indicator of muscle injury. Table 2 lists the common features of diagnosis of rhabdomyolysis and subsequent acute kidney injury. The definitive diagnosis of rhabdomyolysis requires an elevation of CK levels to more than five times normal. The isoenzyme CK-MM (found in skeletal and cardiac muscle) is responsible in large part for the elevation in serum CK; the CK-MB fraction (found primarily in cardiac but also in skeletal muscle) should not exceed 5% of the total CK level. Serum CK generally rises 2–12 h after the onset of muscle injury and peaks 24–72 h, after which it declines at the relatively constant rate of 39% of the previous day's value [55]. Creatinine kinase

Table 2 Diagnosis of rhabdomyolysis and subsequent acute kidney injury (Adapted from Petejova and Martinek [56])

Clinical presentation
Muscular weakness, myalgia, swelling, tenderness, stiffness
Fever, feelings of nausea, vomiting, tachycardia
Oligoanuria or anuria in connection with renal damage or in the presence of volume depletion
Signs/symptoms of associated drug/toxin toxicity
Laboratory findings
Serum: creatinine, urea nitrogen, creatinine phosphokinase, myoglobin, ions (potassium, phosphorus, calcium), lactate dehydrogenase, transaminases, acid–base balance
Urine: myoglobin or positive dipstick test without any erythrocytes

values that fail to decrease in this manner suggest ongoing muscle injury.

Serum myoglobin increases within a few hours of muscle injury, before the increase in serum creatinine kinase. Because the metabolism of protein-bound myoglobin to bilirubin and the renal excretion of free myoglobin occurs rapidly, serum myoglobin concentration are typically normal 1–6 h after cessation of muscle injury in the presence of normal renal function [20]. Consequently, absence of myoglobinuria does not preclude the diagnosis of rhabdomyolysis. Variables that determine the presence of myoglobin in the urine include the glomerular filtration rate, the concentration of plasma myoglobin, the degree of plasma protein binding, and the rate of urine production and flow [57–59].

Dark brown urine, positive for blood on a reagent strip but without red blood cells on microscopic examination, indicates the presence of myoglobin [11]. Although the renal myoglobin threshold is 1 mg/dL, the urine does not become discolored until its myoglobin concentration is great than 100 mg/dL. Urine dipsticks containing orthotoluidine react with the globin fraction of hemoglobin and myoglobin. If red blood cells are present, the orthotoluidine reaction does not differentiate hemoglobin from myoglobin. Radioimmunoassay, immunoelectrophoresis, and hemagglutination are more specific than urine dipstick methods but also significantly more expensive [11].

Muscle cell disruption results in the release of potassium, phosphate, and urate. Acidemia and renal insufficiency may increase serum potassium concentrations further. Hypocalcemia, the result of deposition of calcium in the damaged muscle, may be present with or without acute kidney injury. It is usually clinically insignificant, unless it occurs in the setting of severe hyperkalemia or ventricular dysfunction [45]. In approximately 30% of patients with acute kidney injury and rhabdomyolysis, hypercalcemia occurs in the subsequent diuresis phase of the renal impairment. Parathyroid hormone concentrations are typically normal or low, but 1,25-dihydroxycholecalciferol concentrations are much greater in the hypercalcemic patients than in patients who do not develop hypercalcemia [60].

Aldolase, lactate dehydrogenase, and aspartate transaminase activities are frequently elevated as well but only aldolase is specific for muscle injury. Creatinine may be elevated from both renal insufficiency and from the release of creatine from muscle and its spontaneous hydration to creatinine [11].

Complications

Acute Kidney Injury

The primary complication of rhabdomyolysis is acute kidney injury, which occurs in approximately 30% of patients [56, 61]. Risk factors for acute kidney injury in the setting of drug or toxin exposure are less studied than in traumatic or medical-associated rhabdomyolysis. In general, risk factors for acute kidney injury in the presence of rhabdomyolysis include hyperkalemia, hyperphosphatemia, dehydration, sepsis, intravascular volume depletion, high serum myoglobin concentrations, and low myoglobin clearance [18, 56].

The concentration of heme pigments resulting in acute kidney injury is not well understood. At urine pH less than 5.6, myoglobin dissociates into ferrihemate and globin. Ferrihemate depresses renal tubular transport mechanisms and causes a subsequent deterioration in renal function [14, 62]. Myoglobin (molecular weight 17,500 Da)

may interfere with the endogenous vasodilator nitric oxide, causing a decrease in GFR. Myoglobin and other muscle constituents, such as urate, which is metabolized to uric acid, may deposit in the tubules. Other theories include the presence of oxygen free radicals. Animal experiments show that myoglobin causes renal damage when dehydration is present. Contributing factors seem to be concentrated urine with low urine flow and urine pH less than 5.6. Published clinical reviews conclude that patients with hyperkalemia, hyperphosphatemia, high serum myoglobin concentrations, and low myoglobin clearance seem to be at risk for development of acute kidney injury [9, 18, 63–66].

Other severe systemic complications include disseminated intravascular coagulopathy and acute compartment syndrome from swelling muscle and reduced macrocirculation and microcirculation of injured limbs. Extracted fluid from the circulation into the swollen muscle groups may lead to hypotension and shock [67, 68].

Treatment

There are no randomized, controlled trials in the treatment of rhabdomyolysis that offer definitive guidance for treatment. Only a few interventional clinical trials in rhabdomyolysis have been reported in the past decade. There are even less data for treatment guidelines studying rhabdomyolysis management in the poisoned patient. Most recommendations are based on retrospective observational studies with small numbers of patients, animal models, case reports or series, and opinion. As with other disease states, management guidelines for the poisoned patient are often extrapolated from the care of nonpoisoned patients. The lack of high-quality evidence must be acknowledged and considered when reviewing recommendations for interventions [68].

The treatment of rhabdomyolysis involves several components in the poisoned patient (Table 3). The cornerstone of treatment centers on the prevention of acute kidney injury. No single marker or predictive model has been able to reliably

Table 3 Components in the treatment of rhabdomyolysis in the toxicology patient (Adapted from Zimmerman and Shen [68])

Discontinuation of offending agent causing skeletal muscle injury
Control of sympathomimetic features and/or seizures
Extracellular fluid expansion (Maintain good urine output, stable hemodynamics)
Rapid identification of potentially life-threatening complications
Avoid agents that impair renal blood flow autoregulation (NSAIDs, ACE inhibitors, ARBs)

assess the risk of acute kidney injury, especially in the poisoned patient.

There is complete agreement that early and aggressive volume resuscitation, sufficient to restore adequate renal perfusion and increase urine flow, is the standard of care in preventing acute kidney injury in patients with rhabdomyolysis (Level II-2 recommendation) [2, 68–73]. In animals with rhabdomyolysis that had a low urinary pH, dehydration predisposed to renal injury, which was prevented with urinary dilution [55, 66, 74]. In addition, hypovolemia may occur as a result of movement of fluid into the traumatized muscle and/or to hyperthermia.

The type of fluid and the total volume of fluid remain matters of opinion. A target of 6–12 L within 24 h is a reasonable goal, as long as complications from volume overload can be avoided [68]. Strict observance of adequate urine output should be instituted with a goal rate of 2 mL/kg body weight/h [72]. Although there are no standard protocols in the literature for the duration of fluid administration, intravenous fluids should be continued until the level of creatinine kinase in the plasma decreases to less than 1000 U/L (17 *ukat*/L) or until the development of oliguric acute kidney injury limits further fluid administration [68, 71].

Although research is limited, isotonic saline is preferred because it is readily available and does not contain potassium [68]. A prospective, randomized trial compared the effects of lactated Ringer's versus 0.9% saline administered at 400 mL/h in patients with mild rhabdomyolysis

secondary to doxylamine [75]. At the end of 12 h of infusion, the serum and urine pH were higher in the lactated Ringer's group; however, the clinical significance of this outcome is unclear.

Administering bicarbonate solution to prevent rhabdomyolysis-induced acute kidney injury is a consideration but evidence of a clinical benefit is lacking (Class II-2 recommendation). Clinical reports [76] suggest that alkaline diuresis may be effective in preventing acute renal insufficiency, but there are no prospective randomized studies to support this. The concept of urinary alkalization derives from the known precipitation of myoglobin in an acidic environment, and therefore urinary alkalization (pH <6.5) theoretically can decrease the deposition of myoglobin in renal tubules. Alkalization of the urine may be difficult to achieve without causing a systemic metabolic alkalosis. Conversely, some bicarbonate-containing fluids may be helpful if 0.9% saline administration results in a dilutional metabolic acidosis [68]. A current consensus statement suggests that sodium bicarbonate administration is not necessary and not superior to normal saline diuresis in increasing urine pH [77].

The use of mannitol to promote urine output and prevent acute kidney injury has also appeared in practice and the literature. However, there is even less convincing evidence for mannitol administration (Class III Recommendation). Mannitol has not been evaluated in the poisoned patient as a sole intervention in a controlled trial of rhabdomyolysis. The same small retrospective studies of bicarbonate administered with mannitol in rhabdomyolysis are cited to suggest treatment success with mannitol [78, 79]. Although many mechanisms have been postulated regarding the renoprotective effects of mannitol, prevention of heme protein trapping by diuretic action explains most of the data [63, 80]. A variety of dosing regimens using intermittent bolus and continuous infusion of mannitol are reported. Routine use of mannitol is not recommended for rhabdomyolysis, and it should not be administered to hypovolemic or anuric patients [68].

Similar to mannitol, the use of loop diuretics in the routine management of rhabdomyolysis is not

recommended (Class III recommendation). Diuretics have been advocated to "convert" oliguria or anuria to nonoliguria but with very limited published experience. Care must be taken not to exacerbate hypokalemia or hypocalcemia if loop diuretics are used; conversely, use may be beneficial to treat hyperkalemia before renal recovery or hemodialysis [68].

Renal replacement therapies remain a mainstay of treatment in patients that develop rhabdomyolysis-associated acute kidney injury (Class II-1). Hemodialysis and continuous kidney replacement methods have been investigated in several studies [81–83]. The initiation of renal replacement therapy in clinical practice should not be managed by the myoglobin or creatinine kinase serum concentration but by the status of renal impairment, with complications such as life-threatening hyperkalemia, hypercalcemia, hyperazotemia, anuria, or volume overload without response to diuretic therapy [56, 77, 80]. Myoglobin has a molecular mass of 17 kDa and is poorly removed from circulation using conventional extracorporeal techniques. Therefore, intermittent hemodialysis is mostly mandated by renal or metabolic indications or drug/toxin removal. Preventive extracorporeal elimination is not routinely indicated [56].

Electrolyte disturbances that occur in the setting of rhabdomyolysis should be treated in a standard fashion. Be aware that hyperkalemia may occur within a few hours of onset of rhabdomyolysis and may be severe enough to require intervention [72]. Hyperphosphatemia may require administration of phosphate binders and treatment is dictated by the degree of phosphate elevation. In addition, hypocalcemia may occur early in the clinical course of rhabdomyolysis [66]. However, calcium should not be administered unless hyperkalemia or ventricular dysfunction occurs since calcium infusion may increase deposition of calcium in injured muscle. Hypercalcemia seen during the diuretic phase of acute kidney injury is usually self-limited and requires only conservative treatment and fluid replacement [84].

Prognosis

Outcomes from rhabdomyolysis in the poisoned patient are not known. Considering all causes of rhabdomyolysis, most patients with acute renal failure from rhabdomyolysis recover function within a few months [68]. It is reasonable to extrapolate that mortality of patients with rhabdomyolysis and acute renal failure is likely higher than in patients with no renal failure [78].

Gastrointestinal ADRs	711
Renal ADRs	714
Neurologic ADRs	716
References	722

Adverse drug reactions (ADRs) are undesirable effects of medications used in normal doses [1]. ADRs can occur during treatment in an intensive care unit (ICU) or result in ICU admissions. A meta-analysis of 4139 studies suggests the incidence of ADRs among hospitalized patients is 17% [2]. Because of underreporting and misdiagnosis, the incidence of ADRs may be much higher and has been reported to be as high as 36% [3]. Critically ill patients are at especially high risk because of medical complexity, numerous high-alert medications, complex and often challenging drug dosing and medication regimens, and opportunity for error related to the distractions of the ICU environment [4]. Table 1 summarizes the ADRs included in this chapter.

ADRs are among the leading causes of death in hospitalized patients [1, 5]. Other serious effects include disability, prolonged hospitalization, and increased healthcare costs. These costs are variable depending on the severity, but each ADR could cost \$6000–9000 and increase the length of stay by a median of 8.8 days [4, 6]. One observational study of ICU patients found an incidence of 20.2%, or 80.5 events per 1000 patient days, of which 13% were life threatening and/or fatal [7].

Medical toxicologists can help to decrease healthcare costs and reduce length of stay by assisting with the rapid detection and treatment of ADRs. This benefits both the patient and healthcare system. This chapter will provide a background for identifying ADRs as well as

Table 1 Adverse drug reactions (ADRs) in the ICU chapter overview. ADRs are categorized alphabetically by organ system

Allergic/hypersensitivity ADRs	Angioedema
	Bronchospasm
	Infusion reactions
	DRESS
Dermatologic ADRs	SJS and TEN
Cardiovascular ADRs	Arrhythmias and conduction disturbances
	QT prolongation
	Hypotension
	Cardiogenic shock
	Distributive shock
Hematologic ADRs	Thrombocytopenia
	Methemoglobinemia
Pulmonary ADRs	Drug-induced respiratory disease
	Airway dysfunction
	Parenchymal and interstitial lung disease
	Pulmonary edema and vasculopathy
	Pulmonary arterial hypertension
	Neuromuscular respiratory disease
Gastrointestinal ADRs	Constipation/ileus
	Delayed absorption
	Diarrhea
	Hepatotoxicity
	Pancreatitis
Renal ADRs	Acute renal failure: prerenal, intrarenal, and postrenal nephrotoxicity and nephrotic syndrome
Neurologic ADRs	Delirium
	Seizures

Abbreviations: drug reaction with eosinophilia and systemic symptoms (*DRESS*), Steven–Johnson syndrome, toxic epidermal necrolysis (*TEN*)

describing various types. ADRs will be summarized by organ system, incorporating post-marketing surveillance to identify higher-risk ICU drugs. Drugs commonly used in the ICU for the management of poisoned patients are the primary focus of this chapter.

Table 2 Naranjo Adverse Drug Reaction Probability Scale. A ten-question probability scale assigns points to each response. If the response is unknown, a score of 0 is assigned. From the total score, drug–ADR causality can be stratified as definite (≥ 9), probable (5–8), possible (1–4), and doubtful (≤ 0)

	Question	Yes	No
1	Previous reports on this reaction?	+1	0
2	Timing-ADR appear after drug administration?	+2	−1
3	Did the ADR improve after the drug was discontinued or after an antagonist was administered?	+1	0
4	Did the ADR reappear when the drug was readministered?	+2	−1
5	Are there alternative causes (other than the drug) that could on their own have caused the reaction?	−1	+2
6	Did the reaction reappear when a placebo was given?	−1	+1
7	Was the drug detected in blood (or other fluids) in concentrations known to be toxic?	+1	0
8	Was the reaction more severe when the dose was increased or less severe when the dose was decreased?	+1	0
9	Did the patient have a similar reaction to the same or similar drugs in any previous exposure?	+1	0
10	Was the ADR confirmed by any objective evidence?	+1	0
	Total:		

Modified from Naranjo et al. [8]

Background

When an ADR is suspected, a Naranjo probability score can be used to standardize the assessment, with presumed causality assigned based on total score (see Table 2) [8].

The higher the score, the more likely an ADR occurred. Mechanisms by which these medications cause ADRs include pharmacogenetic, pharmacokinetic, and metabolite accumulation and/or combinations and are described in Table 3. Table 4 summarizes one commonly used scoring system for grading adverse drug reactions.

The incidence of specific drug–ADR combinations is low, requiring large databases and statistical analysis to identify emerging trends. Advances in information technology have

allowed pharmacovigilance and post-marketing surveillance systems to calculate observed to the expected number of drug-event pairs (proportional reporting ratios (PRRs)) [9–13]. The Empirical Bayesian Geometric Mean (EBGM) is calculated from the PRR and accounts for differences in reporting rates and variables within the dataset [14]. False positives, which are inherent to data mining systems, are avoided by increasing the number of reports and increasing PRR or EBGM, thereby strengthening the signal [12, 14]. Both PRR and EBGM ratios shrink toward one, and values ≥ 2 are considered to be the safety signal thresholds that warrant further evaluation. Previous studies have suggested PRRs to be more sensitive and EBGM more specific [12, 15]. Some studies minimize false negatives by using more than one data mining system;

however, well-known drugs associated with ADRs continue to be missed, which is possibly secondary to underreporting. These are often older medications such as nitroglycerine infusions [16]. There are limited literature studies on ICU ADRs compared to medication error evaluation.

Organ System ADRs

Allergic/Hypersensitivity ADRs

Infusion Reactions

Infusion reactions (drug-mediated hypersensitivity, infusion-related toxicity, cytokine storm, cytokine-release syndrome, anaphylactoid reaction, and serum sickness-like illness) are associated with a spectrum of variability and heterogeneity for both individual and drug; symptoms may include anxiety, diaphoresis, rigors/chills, fever, pruritus, urticaria, angioedema, headache, nausea, emesis, diarrhea, chest pain, dyspnea, wheezing/bronchospasm, hypoxia, respiratory failure, hypotension, and death [17–21]. Symptoms can occur shortly after the infusion begins but can have delayed onset; symptoms may decrease when the infusion rate is discontinued or slowed but symptoms may persist.

Drug classes associated with infusion reactions include antimetabolites (drugs interfering with nucleic acid synthesis), antimicrobials, electrolytes and nutrients, enzymes, and immunomodulators [17]. The implicated final common pathway for each medication may include mast cell

Table 3 Types of ADRs

1	Exaggeration of drug's normal/desired pharmacological mode of action
2	Continuing action/reaction, persisting for longer than expected time period
3	Delayed onset of action
4	Withdrawal
5	Unexpected failure of therapy
6	Idiosyncratic response not expected from normal pharmacological mode of action
7	Drug–drug interaction
8	Other pharmacokinetic interaction
9	Other pharmacodynamic interaction

Modified from American College of Medical Toxicology ToxIC Database available at <http://www.acmt.net/cgi/page.cgi/Toxic1.html>

Table 4 CTCAE grading of adverse drug reactions. ADRs can be mild or moderate or result in death; signs/symptoms, interventions, and limitations to ADLs are used to grade the severity with a score of 1–5

Grade	Description	Signs/symptoms	Intervention	ADLs
1	Mild	Asymptomatic or mild	None	
2	Moderate	Minimal	Noninvasive intervention	Limited
3	Severe	Significant but not immediately life threatening	Hospitalization and/or prolongation	Disabling
4	Life threatening	Life-threatening consequences	Urgent intervention indicated	Disabling
5	Death			

Modified from the US Department of Health and Human Services Common Terminology Criteria for Adverse Events (CTCAE) Version 4.0 available at <http://evs.nci.nih.gov/ftp1/CTCAE/About.html> (Accessed Aug 18, 2015)

Abbreviations: ADL activities of daily living, CTCAE common terminology criteria for adverse events

activation and nitric oxide (NO) signaling via nitric oxide synthase (e.g., *N*-acetylcysteine [22, 23] and calcium [24]), NO donors and NO-like compounds (e.g., nitroprusside [25]), reactive oxygen and nitrogen species (e.g., amphotericin [26]), S-nitrosylation and transnitrosylation (e.g., adenosine [27–29], iron, *N*-acetylcysteine, and nitroprusside), histamine release (e.g., amphotericin [26], *N*-acetylcysteine [20], and vancomycin [30]), and cytokine release (e.g., amphotericin [26], *N*-acetylcysteine [20], and immunoglobulins) [31–34]. Sometimes, clinical effects are caused by an excipient such as polyethoxylated castor oil which has been used as the solubilizing vehicle for phytonadione [35]. Some drugs such as *N*-acetylcysteine have been prospectively studied. When administered rapidly, *N*-acetylcysteine has caused mild, moderate, and severe infusion reactions for up to 60%, 30%, and 10% of patients, respectively [20]. This association may be underreported, as this drug does not appear in the table of drugs associated with infusion reactions. The medical toxicologist may see infusion reactions related to IV *N*-acetylcysteine, although slower infusion rates have made this less common [20, 21, 23, 36, 37].

For ICU patients, electrolytes had the highest association with infusion reactions followed by immunomodulatory drugs, antiarrhythmics, antifungals, and antibiotics (Table 5). Treatment involves discontinuing or slowing the rate of infusion for the suspected drug or pretreating with antihistamine and prostaglandin inhibitors.

Drug-Induced Angioedema

Angioedema, or rapid localized edema of the deep dermis, subcutaneous, or submucosal tissues, can be idiopathic, or it can be mediated by bradykinin or mast cells [38]. Angioedema associated with the use of drugs can manifest after the first dose of a drug, but for some drugs, such as those targeting the renin–angiotensin–aldosterone system, it can occur at any time [39]. The presence of angioedema with wheals or urticaria suggests the etiology involves mast cells. Culprit medications include nonsteroidal anti-inflammatory drugs (NSAIDs) or antibiotics, often acting through the inhibition of cyclooxygenase resulting in alteration in the metabolism of arachidonic acid with increased leukotrienes [40–42]. Angioedema without wheals or urticaria could be bradykinin mediated, which implicates angiotensin-converting enzyme inhibitors [38]. Bradykinin

Table 5 ICU drugs highly associated with infusion reactions from two post-marketing surveillance systems: Molecular Analysis of Side Effects (*MASE*) and the FDA’s Adverse Event Reporting System (*FAERS*). Statistical criteria for *MASE* was set as $PRR \geq 2.0$ and $N \geq 30$

reports and for *FAERS* as $EBGM \geq 2.0$ and $N \geq 30$ reports. Drugs are grouped by drug class and then displayed with comparison data. Using two systems improved the sensitivity of drug detection

Classification	Generic name	FAERS		MASE	
		<i>N</i>	EBGM	<i>N</i>	PRR
Analgesic	Meperidine	–	–	32	3.9
Antiarrhythmic	Adenosine	29	19.4	33	18
Antibiotic	Meropenem	–	–	34	3.1
	Ceftriaxone	20	1.3	33	3.1
	Vancomycin	109	6.8	162	4.7
Antifungal	Amphotericin B	58	7.0	66	4.9
Electrolytes	CaCl and KCl	34	26.6	8	1.7
	Ferric Na Gluc	55	37.6	–	–
	Iron dextran	68	48.1	66	48.9
	Iron sucrose	57	27.0	–	–
Immunomodulator	Ig	314	17.4	68	9
	Rho-Ig	32	13.3	–	–
Mucolytic	Acetylcysteine	16	5.0	25	2.8

Abbreviations: calcium (*Ca*), chloride (*Cl*), immunoglobulin (*Ig*), and potassium (*K*)

accumulation results in an increased vascular permeability resulting in angioedema [42].

Drugs acting on the renin–angiotensin–aldosterone system are commonly implicated, but several other classes have also been implicated including antibiotics, aspirin, NSAIDs, antifungals, calcium channel blockers, diuretics, and lidocaine [43–45]. ACE inhibitors [ACEI] have been associated with angioedema, and incidence rates for specific drugs have been reported for captopril (7.17 events per 1000 persons) [46], enalapril (6.85 events per 1000 persons) [45], lisinopril (4.09 events per 1000 persons) and ramipril (2.92 events per 1000 persons) [47]. Other studies have reported cumulative incidence of angioedema per 1000 persons for the class of ACEIs as 1.79, 1.80, and 2.95 [39, 48, 49]. Comparing drugs targeting the renin–angiotensin–aldosterone system, one cohort study found risk for angioedema three times

higher for ACEIs and renin inhibitors than for the control group (Table 6) [39].

Treatment involves stopping the implicated medication(s) and monitoring the patient for at least 6 h [42, 50]. If angioedema is secondary to mast cell activation, antihistamines, epinephrine, and corticosteroids may be effective. These will be less effective if bradykinin is implicated [50]. Cases of ACEI-induced angioedema can continue to occur for weeks despite discontinuing therapy [42]. If an ACEI is implicated, changing to angiotensin receptor blockers is associated with a 10% risk of angioedema recurrence [51]. When bradykinin-mediated angioedema is suspected and life threatening, bradykinin antagonists (e.g., icatibant) and C1 inhibitor concentrates (e.g., ecallantide, an inhibitor of kallikrein) may be effective, but their cost is prohibitive for routine use [42, 50,

Table 6 Comparative risk of angioedema (AE) associated with drugs that target the renin–angiotensin–aldosterone system (Modified from Toh et al. [39]). Incidence rates were calculated for angiotensin receptor blockers (ARBs) and compared to the entire class of angiotensin-converting enzyme inhibitors (ACEIs) using beta-blockers as a control

group as they are generally not thought to be associated with AE. Incidence reported per 1000 persons with 95% confidence interval. Hazard ratio reported with 95% confidence interval. Severe reactions were those that required ICU admission

Class/generic name	N	Incidence	HR	N (severe)	Incidence (severe)	HR (severe)
ACEIs	3301	1.79 (1.73–1.85)	3.04 (2.81–3.27)	326	0.18 (0.16–0.20)	4.91 (3.62–6.65)
ARBs	288	0.62 (0.55–0.69)	1.16 (1.00–1.34)	10	0.02 (0.01–0.04)	0.56 (0.28–1.14)

[52, 53]. Fresh frozen plasma contains angiotensin-converting enzyme and C1 esterase inhibitor and can reverse bradykinin-mediated angioedema [52, 53].

Drug-Induced Bronchospasm

A Swiss post-marketing surveillance system found that bronchospasm was present in 2% of reported ADRs; 55% of these cases are classified as serious [54]. Implicated drug classes include analgesics and NSAIDs in 24% (64.5% serious), antimicrobial agents in 18% (52% serious), cardiovascular drugs in 11% (50% serious), and excipients in 5.5% (41% serious) [54]. The nonsterile nebulized bronchodilator solutions contain preservatives that can induce concentration-dependent bronchospasm: sulfites, benzalkonium chloride, or ethylenediaminetetraacetic acid [55]. The critical care toxicologist should keep drug-induced bronchospasm in the differential in the ventilated patient who has a change in oxygenation.

Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS)

Drug reaction with eosinophilia and systemic symptoms (DRESS) is associated with high mortality (47%) and is characterized by an exanthema with facial edema, enlarged lymph nodes, eosinophilia, and high-grade fever [56]. The severity depends on the organs involved (hepatitis, acute renal failure, pneumonitis, myocarditis, hemophagocytic syndrome, encephalitis, and/or multi-organ failure) [57]. DRESS can be easily missed as sometimes the eosinophilia is delayed and skin manifestations vary in severity from mild to severe [58]. Drugs associated with DRESS will usually have been prescribed for at least 2 weeks and include anticonvulsants (e.g., carbamazepine and lamotrigine), sulfonamides, and antibiotics (e.g., amoxicillin, ciprofloxacin, and minocycline) [59–61]. Discontinue all suspected drugs and treat supportively for organ failure and shock. Severe cases may require corticosteroids, intravenous immunoglobulins, and/or antiviral drugs (e.g., ganciclovir) because DRESS can closely resemble herpes

virus reactivation with eosinophilia and systemic symptoms (“VRESS”) [57, 58].

Dermatologic ADRs

Steven–Johnson Syndrome and Toxic Epidermal Necrolysis

Steven–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are severe and potentially life-threatening systemic disorders characterized by skin and mucous membrane lesions, sometimes with necrosis. The extent of the surface area involved as well as the presence of necrosis helps to differentiate them. The lesions typically appear on extensor surfaces as well as the palms or the hands and soles of the feet. If there is epidermal and mucous membrane detachment and more than 30% of the body surface area is involved, TEN is implicated. Drugs implicated in SJS and/or TEN are pharmacologically diverse. Data mining implicates multiple pathways and suggests metabolizing enzymes, and transporters increase the intracellular tissue concentrations of reactive metabolites resulting in oxidative stress and the immunologic response. A disproportionate number of drugs associated with SJS were metabolized by cytochrome P450 3A4 and 2C9 and implicated transporters, multidrug resistance protein 1 (MRP-1), organic anion transporter 1 (OAT1), and PEPT2 [62]. Drug targets highly associated with SJS included cyclooxygenases 1 and 2, carbonic anhydrase 2, and sodium channel 2 alpha which overlaps with results of other studies implicating antiepileptic drugs [63]. See Table 7 for drugs identified by the US Food and Drug Administration’s (FDA) Adverse Event Reporting System (FAERS) as being highly associated with SJS. The FDA has issued post-marketing safety alerts for acetaminophen (warning), phenytoin (modified warning), and carbamazepine (boxed warning). Critical care patients often require treatment with drugs highly associated with SJS; treatment involves discontinuing the suspected

Table 7 MASE and FAERS ICU drugs highly associated with Steven–Johnson syndrome when $PRR \geq 2$ or EBGM ≥ 2 and $N > 30$

Analgesics: acetaminophen
Antiepileptics: carbamazepine, lamotrigine, phenytoin, zonisamide
Antimicrobials: amoxicillin, ampicillin/sulbactam, amphotericin B, azithromycin, cefdinir, cefepime, ceftriaxone, cefotaxime, cefuroxime, cephalexin, ciprofloxacin, clarithromycin, clindamycin, erythromycin, fluconazole, meropenem, piperacillin/tazobactam, rifampin, sulfamethoxazole, trimethoprim, vancomycin
Barbiturates: phenobarbital
Diuretics: furosemide, torsemide
Mucolytics: acetylcysteine
Proton pump inhibitors: pantoprazole
Vitamins: phytonadione

drug(s) and continuing care in facilities experienced in burn care.

Cardiovascular ADRs

Drug-Induced Arrhythmias and Conduction Disturbances

Arrhythmias and conduction disturbances range from bradycardia to tachycardia, can originate anywhere from the atria to the ventricles, can be regular or irregular, and can be mild or life threatening. Many of the toxin-induced arrhythmias are discussed throughout the medication chapters including cardiovascular digitalis glycosides, beta-receptor antagonists, cardiovascular calcium channel blocking agents, cyclic antidepressants, and lithium.

Drug-Induced QT Prolongation

This section discusses ADRs associated with QT prolongation; for additional details, refer to ► Chap. 22, “Toxicant-Induced Torsade de Pointes.” QT prolongation is highly prevalent in the ICU, and one prospective study found 24% of patients in a mixed ICU had QTc > 500 ms [64]. QT prolongation can result from hypokalemia, hypomagnesemia, hypocalcemia, genetic predisposition (ion channel polymorphisms),

tissue hypoxia, and/or the presence of one or more drugs with potassium-blocking properties. A nomogram exists and should be used to correct for heart rate [65]. For a reference list of QTc prolonging medications, the Arizona Center for Education and Research on Therapeutics (AZCERT) continually updates their list (www.crediblemeds.org). The concurrent use of drugs inhibiting cytochrome 3A4 or 2D6 should also be recognized in the setting of QT prolongation [66–69].

Torsades de pointes (TdP), a potentially fatal ventricular arrhythmia, is associated with QT prolongation but usually requires at least one other risk factor before emerging. One review of QTc prolongation and TdP found 92.2% of TdP cases had at least one additional risk factor for QTc prolongation [70]. In reviews of thorough QT studies, while drug-associated QTc prolongation is associated with and considered a surrogate for predicting TdP, other intrinsic and extrinsic factors modify this risk. Bradycardia may be a major risk factor for TdP; TdP rarely occurs when HR is above 105 beats per minute [65]. A large case-crossover study of more than 17,000 patients who were prescribed with antipsychotic drugs found a drug’s arrhythmogenic propensity was related to dose, blockade of potassium channel, and short-term usage [71]. For antipsychotic drugs, the strength of potassium blockade from lowest to highest was quetiapine, chlorpromazine and trifluoperazine, clozapine, aripiprazole, prochlorperazine, olanzapine, zotepine, risperidone, thioridazine, ziprasidone, and haloperidol [71]. Beside potassium channel blockade, tachycardia associated with muscarinic blockade may be a risk factor for cardiotoxicity [72]; however, another large retrospective review of antipsychotic ingestions admitted to a medical toxicology service demonstrated tachycardia may be protective [65]. ICU drugs associated with QTc as listed by AZCERT are highlighted in Table 8.

The treatment for QT prolongation includes discontinuing associated drugs and replacing associated electrolyte deficiencies. Resolution of prolongation will depend on the pharmacokinetics of implicated drugs. Sodium bicarbonate and

Table 9 Algorithm for the initial assessment of shock. When there are signs of tissue hypoperfusion (altered mental status, mottled/clammy skin, decreased urine output, tachycardia, and/or elevated lactate), an assessment of the

type of circulatory shock begins with estimating CO or SvO₂. Echocardiography can be used to differentiate circulatory shock

Type	CO or SvO ₂	CVP	Echocardiograph	
			Cardiac chambers	Cardiac contractility
Distributive	Normal or high		Normal	Normal
Hypovolemic	Low	Low	Small	Normal or high
Cardiogenic	Low	High	Large ventricles	Poor
Obstructive	Low	High	Small ventricle(s) depending on location of obstruction	

Modified from Vincent and Backer [76] *Abbreviations: CO* cardiac output, *CVP* central venous pressure, *SvO₂* mixed venous oxygen saturation

hyperventilation should be used in the setting of concurrent QRS prolongation; sodium bicarbonate is not known to change QTc [73, 74]; refer to ► [Chaps. 21, “Cardiac Conduction and Rate Disturbances”](#) and ► [22, “Toxicant-Induced Torsade de Pointes”](#) for further information on the management of these patients.

Drug-Induced Hypotension

This section discusses ADRs associated with hypotension; for additional details, refer to ► [Chap. 14, “The Assessment and Management of Hypotension and Shock in the Poisoned Patient”](#) Drug-induced hypotension can occur in up to 35% of ICU patients, and the most prevalent medications include cardiovascular medications, sedatives, and

analgesics [75]. Hypotension may be hypovolemic (intravascular volume loss), distributive (vasodilation or smooth muscle relaxation), cardiogenic (decreased cardiac output via decreased conduction velocity, contractility, and/or heart rate), and/or obstructive (e.g., pulmonary embolism, cardiac tamponade, or tension pneumothorax) [76]. Drug-induced hypotension often involves a combination of hypovolemic, distributive, and/or cardiogenic mechanisms. Table 9 is an overview of the initial assessment of shock, and Table 10 lists ICU drugs associated with hypotension with their known mechanism. For details of the treatment of hypotension, refer to ► [Chap. 14, “The Assessment and Management of Hypotension and Shock in the Poisoned Patient.”](#)

Table 10 ICU drugs associated with hypotension. Common ICU drug classes are listed with examples of generic drugs implicated. Mechanism of hypotension included hypovolemia, distributive (vasodilation), and/or cardiogenic (decreased CO)

Classification		Generic name	Mechanism		
			Hypovolemia	Vasodilation	Decreased CO
Beta-blockers	Selective	Atenolol, bisoprolol, esmolol, and metoprolol			B1B
	Nonselective	Carvedilol		A1B, B2B	B1B
		Labetalol		A1B, B2B	B1B
		Propranolol		B2B	B1B
		Nadolol		B2B	B1B
		Sotalol		B2B	B1B
CCB	Dihydropyridine	Amlodipine, nicardipine, and nifedipine		L-type CCB	
	Non-dihydropyridine	Diltiazem and verapamil		L-type CCB	L-type CCB
Diuretics	Thiazide	Hydrochlorothiazide	inh. Na/Cl symporter		
	Thiazide-like	Metolazone	inh. Na/Cl symporter		
	Potassium sparing	Spironolactone	inh. Na/K exchanger and competitive aldosterone ant.		
	Loop	Bumetanide and furosemide	inh. Na-K-2Cl symporter		
Imidazolines		Clonidine and dexmedetomidine		A2A	
Nitrates		Isosorbide dinitrate and nitroglycerine		NO	
Opioids		Morphine, codeine, hydromorphone, meperidine, fentanyl		Decrease sympathetic outflow, H2	Decreased sympathetic outflow
Renin-angiotensin antagonists	ACEI	Benazepril, fosinopril, lisinopril, and ramipril	Bradykinin natriuresis	Bradykinin	
	ARBs	Candesartan, irbesartan, losartan, and valsartan		ARB	
Sedative/hypnotics		Propofol		Decreased sympathetic outflow	Decreased sympathetic outflow
	Barbiturates	Phenobarbital and pentobarbital		Decreased sympathetic outflow	Decreased sympathetic outflow
	Benzodiazepines	Lorazepam and midazolam		Decreased sympathetic outflow	Decreased sympathetic outflow
Vasodilators		Hydralazine			

Abbreviations: ACEI angiotensin-converting enzyme inhibitor, *ant* antagonist, ARB angiotensin II receptor blocker, A1B alpha-1-adrenergic receptor blocker, A2A alpha-2-adrenergic receptor agonist, B1B beta-1-adrenergic receptor blocker, B2B beta-2-adrenergic receptor blocker, CCB calcium channel blocker, Cl chloride, CO cardiac output, inh inhibitor, K potassium, Na sodium, NO nitric oxide

Drug-Induced Cardiogenic Shock

Drugs associated with cardiogenic shock include β 1-adrenergic antagonists, muscarinic agonists, and L-type calcium channel antagonists. β 1-adrenergic antagonists decrease heart rate, conduction velocity, and contractility. Muscarinic receptor subtype M2 agonists decrease heart rate and cardiac conduction velocities [77, 78]. Calcium channel blockers acting at L-type channels decrease cardiac contractility, conduction velocity, and/or heart rate; dihydropyridine calcium channel blockers are associated with vasodilation, while nondihydropyridines are also associated with decreased cardiac output [79]. Sedatives and analgesics decrease sympathetic outflow that decreases norepinephrine and epinephrine release resulting in both vasodilation and decreased cardiac output.

Drug-Induced Distributive Shock

Vasodilation can result from L-type calcium channel antagonists, angiotensin receptor blockers (ARBs), α 1-adrenergic antagonists, α 2-adrenergic agonists, β 2-adrenergic antagonists, bradykinin receptor agonists, histamine H2 receptor agonists, muscarinic M3 antagonists, and/or prostaglandin E2, D2, and I2 agonists [77, 78, 80–83]. Drugs impacting NO signaling will cause vasodilation when concentrations of either NO or cyclic-guanosine monophosphate are increased. Histamine release can occur proportionately to drug dose and has been associated with drugs such as opioid analgesia and antibiotics such as vancomycin (see section on “[Infusion Reactions](#)” for additional drugs associated with histamine release). A double-blind study found meperidine was most frequently associated with histamine release, but morphine and codeine have also been implicated [84]. Opioids can also cause hypotension through vasodilation and vagal activation [85].

Opioids

Opioid receptors are located peripherally and centrally; they are involved in vascular regulation and decrease sympathetic neural regulation [86–88]. Mu-, delta-, and kappa-opioid receptors participate in the complex vasoregulatory process and when blocked centrally decrease hypotension

[89–93] and narrow the ability to autoregulate blood flow [94].

Propofol

Propofol is an anticonvulsant and amnestic with rapid onset and short duration of action [95]. Due to its faster recovery time and return of spontaneous respiration time, propofol has been favored by some over benzodiazepines for procedural sedation and for patients in the ICU [95–97]. Propofol is structurally unrelated to other sedative-hypnotics and produces its effects in a dose-dependent manner. Propofol causes hypotension and bradycardia with an average maximum mean arterial pressure (MAP) reduction of 29% after initiation, and severe hypotension develops in 26% of patients [97, 98]. Hypotension occurs through centrally mediated venodilation, sympatholysis and vagolysis [99, 100]. Pretreatment with ketamine, ephedrine, dopamine, or naloxone may decrease risk [101–105], as does the use of the lowest effective dose [106]. Intravenous fluid administration does not appear to be an effective prevention [107, 108].

Propofol is a mitochondrial toxin and can inhibit intracellular energy production resulting in propofol-related infusion syndrome (PRIS) [109]. Signs of PRIS include metabolic acidosis, lipemic serum, rhabdomyolysis, cardiac arrhythmias, acute renal failure, hepatomegaly, and cardiac arrest [109]. PRIS has been associated with longer duration of infusion (>48 h) and faster infusion rates; other risk factors include increased catecholamine and glucocorticoid serum levels, head injury, and respiratory failure [109, 110]. An increase in triglyceride concentration is the most widely accepted marker of PRIS and may be explained by the fat content of the propofol emulsion [109, 110]. PRIS occurs in less than 5% of critically ill patients receiving propofol [109, 111]. One large retrospective study found a mortality of up to 40% in persons with PRIS; a review of FDA MedWatch data found mortality increased to 30% [109, 112]. A predictive tool was created and assigns points based on the presence of six factors: age \leq 18, cardiac manifestations, metabolic acidosis, renal failure, hypotension, and rhabdomyolysis. Mortality increases with each point from 24% to 83% [112]. If PRIS is

suspected, propofol should be immediately discontinued. If the patient continues to decline, extracorporeal membrane oxygenation has successfully treated cardiac arrest [113, 114].

Treatment

The treatment for hypotension is based on the identified cause. The “VIP” approach guides first steps in therapy: ventilate (oxygenate), infuse (fluid administration), and pump (administration of vasoactive agents) [115]. Initially, resuscitation should be done with crystalloid fluids (Level of Evidence [LoE] I) followed by placement of a central venous catheter if refractory hypotension requires vasoactive agents. The end point for fluid resuscitation is when cardiac output is preload independent [76]. Measuring SvO₂ (LoEI) and serum lactate concentrations (LoE_I) can help guide therapy although additional technologies are evolving. Vasoactive agents include vasopressors and inotropes and should be initiated on a case by case basis, considering each drug’s potential adverse reaction profile. Vasopressors cause vasoconstriction from agonism at the β_2 - and α_1 -adrenergic receptors. Inotropes increase cardiac output through agonism at the β_1 -adrenergic receptor (increases heart rate, conduction velocity, and contractility). Adverse effects are related to dose, mechanism, potency, drug–drug, and/or drug–disease interactions.

Inotropic Agents

β -adrenergic agonists increase the heart rate and contractility which may increase the risk of myocardial ischemia in some circumstances [116]; however, a double-blind study found no difference in troponin elevation for treated patients with septic shock [117]. Dobutamine has predominantly beta-adrenergic properties and increases cardiac output and is a consideration when hypotension is mediated by cardiac pump dysfunction. Dobutamine has not demonstrated improved perfusion parameters in patients with septic shock without cardiac failure [118].

Vasopressors

By definition, vasopressors cause vasoconstriction, which can impair tissue perfusion.

Epinephrine’s range of effects is strongly dose dependent. At low doses (usual dosing range 0.01–0.1 microgram/(kg*min)), epinephrine predominantly targets β -adrenergic receptors; however, as the dose increases, more significant α -adrenergic effects appear [116]. Epinephrine has been associated with arrhythmias, decreased splanchnic blood flow, and increased blood lactate concentrations [119, 120]. Dopamine is an immediate precursor to norepinephrine in the synthetic catecholamine pathway [116]. Dopamine is an agonist at dopamine and β -adrenergic receptors at lower doses ($<10 \mu\text{g}/(\text{kg}\cdot\text{min})$), but with higher doses ($10\text{--}20 \mu\text{g}/(\text{kg}\cdot\text{min})$), α -adrenergic effects predominate [76]. The predominant dopaminergic effects observed with low doses of dopamine ($<3 \mu\text{g}/\text{kg}/\text{min}$) may preferentially dilate the hepatosplanchnic and renal circulations, but controlled trials have not shown clinically significant protection from renal dysfunction [121]. “Renally dosed” dopamine theoretically could worsen vasodilation resulting in hypotension, and many toxicology patients have minimal tolerance for worsened blood pressure. Dopamine may increase the incidence of arrhythmia when compared to norepinephrine [122]. Beta doses of dopamine ($<10 \mu\text{g}/(\text{kg}\cdot\text{min})$) may cause further vasodilation and worsen hypotension. Therefore, for critically ill patients, dopamine therapy should be initiated at alpha receptor active doses ($\geq 10 \mu\text{g}/\text{kg}/\text{min}$).

Norepinephrine should be considered as the first-line vasopressor. Several studies demonstrate no advantage of dopamine over norepinephrine, and dopamine is associated with increased rates of arrhythmias and 28-day mortality for patients with cardiogenic and/or septic shock [122, 123]. For tricyclic antidepressant poisoned patients with hypotension refractory to intravenous fluid and serum alkalinization, norepinephrine appeared superior to dopamine as a first-line vasopressor agent [124] (LoE II-3). Norepinephrine may be associated with greater risk for peripheral ischemia and necrosis; however, these effects can occur with other vasopressors including vasopressin, dopamine, and epinephrine; preexisting vascular disease, sepsis, and DIC may be risk factors [116, 125–131].

Hematologic ADRs

Drug-Induced Thrombocytopenia

Thrombocytopenia is a commonly encountered abnormality in the critically ill, occurring in up to 44% of patients. Between 10% and 25% of these cases are thought to be drug induced. Potential mechanisms for this are platelet consumption or destruction, impaired platelet production, and hemodilution [132]. Multifactorial etiology is usually suspected when drug-induced thrombocytopenia (DITP) has occurred; however, single agents are not excluded. Platelets become targeted for destruction when a drug causes an antibody response. Depending on the molecular weight of the drug, this could be hapten dependent (e.g., penicillin) via covalent bonds to platelet glycoproteins or drug dependent (e.g., sulfonamide antibiotics), forming a complex or conformational change [133]. Sometimes autoantibodies are produced that can persist long after drug exposure and result in chronic autoimmune destruction [133].

DITP typically occurs 1–2 weeks after beginning a new drug or suddenly after a single dose of a drug which has previously been taken [134, 135]. Exceptions include first doses of antithrombotic agents such as tirofiban [136–139]. Table 11 contains a list of ICU drugs associated with thrombocytopenia. Antibiotics are associated with thrombocytopenia and, because of their prevalent use in ICU patients, are commonly implicated. Case-control studies have associated quinolones and trimethoprim/sulfamethoxazole with thrombocytopenia [140, 141]. Sample size, exposure rates, and the potential effect of drug combinations likely limited their findings to only these drugs as there are over a thousand case reports of DITP. A database can be found online at <http://www.ouhsc.edu/platelets/ditp.html>. Other drugs to consider for ICU patients include antifungals, antivirals, anticonvulsants, and glycoprotein IIb/IIIa inhibitors and anticoagulants [141].

Heparin or low-molecular-weight heparin is frequently used in immobile ICU patients. These drugs require careful consideration when evaluating a patient for thrombocytopenia.

Heparin-induced thrombocytopenia (HIT) type 2 occurs in 0.5–5% of patients receiving heparin products [142]. Typically this syndrome is characterized by a 50% or greater thrombocytopenia from baseline, occurring 5–15 days after initial heparin therapy. It can occur sooner if there was a prior exposure to heparin. Physiologically, IgG antibodies bind heparin and platelet factor 4 (PF4), forming complexes. These complexes bind platelets and result in thrombocytopenia. If thrombin is activated, thrombosis can occur. If HIT is considered, an HIT score should be calculated to guide therapy. If the HIT score is low (0–3 points), heparin therapy should be continued. For moderate or high scores, further testing is recommended, and the patient started on alternative anticoagulation until the diagnosis can be conclusively excluded. The absence of PF4 IgG antibodies has a high negative predictive value and rules out HIT; specificity is poor so positive tests require additional analysis [142–145]. Serotonin release assay has high specificity (95–100%) and positive predictive value for HIT; however, the availability is limited. Several days are often required for results. Once HIT has been confirmed, duration of therapy should be for 4 weeks or until baseline platelet counts are restored. In the presence of thrombosis, treatment should be continued for 4 months.

When other drugs are suspected, they should be discontinued and platelets monitored for recovery. Recovery time will depend on the pharmacokinetics of the offending drug and the implicated mechanism. Usually, recovery begins 1–2 days after the offending drug has been discontinued and is complete within 1 week [134]. Drug-dependent antibodies can persist for years; patients should be counseled to avoid the implicated drug. See ► Chap. 30, “Toxicant-Induced Hematologic Syndromes” for more detail.

Drug-Induced Methemoglobinemia

Methemoglobinemia is discussed in ► Chap. 30, “Toxicant-Induced Hematologic Syndromes.” Methemoglobinemia can be caused by dapsone

Table 11 ICU drug-induced thrombocytopenia (DITP). Drugs are grouped by drug class and mechanism with number of reports and probability score and if an antibody has been detected. University of Oklahoma Health Sciences Center's DITP database was referenced on May

6, 2015, for number of cases from individual and group patient reports. Drugs were added from recently published literature. Additional drugs, in parentheses, were added from recently published literature

or local anesthetics placed into the pharynx before nasogastric or orogastric tube placement or other procedures [146–157]. Local anesthetics associated with methemoglobinemia include benzocaine, cocaine, lidocaine, and prilocaine [146, 148, 149, 152, 154–157]. Benzocaine treatment may produce more methemoglobin than lidocaine [158]. Methylene blue is the antidote, but should be dosed carefully as logarithmic dosing errors or very high doses could worsen methemoglobinemia [159, 160].

Pulmonary ADRs

Drug-Induced Respiratory Disease

This section discusses ADRs associated with respiratory disease. For additional reference, see ► Chaps. 100, “Irritant and Toxic Pulmonary Injuries” and ► 16, “Treatment of Acute Respiratory Distress Syndrome in the Poisoned Patient.” Respiration requires the integration of multiple systems. Respiratory failure occurs when any part of this process becomes dysfunctional and is

unable to maintain normal pH and/or adequate tissue oxygenation. Types of drug-induced respiratory disease can be subdivided based on location: airway (small and/or large), parenchymal/interstitial/pleural lung disease, pulmonary vasculopathy (e.g., noncardiogenic pulmonary edema or pulmonary arterial hypertension), neuromuscular respiratory disease (e.g., decreased respiratory drive), and/or circulation (e.g., methemoglobinemia) [161–164]. Neurologic drug-induced respiratory disease is common in the ICU due to the number of sedatives and analgesics administered. When evaluating for drug-induced respiratory disease, initial attention to oxygenation, respiratory rate, and end tidal CO₂ is helpful to determine if respiratory depression is present. Hypercarbia is more sensitive than hypoxia for early respiratory depression, and occasionally respiratory depression occurs in the absence of moderate to severe neurologic abnormality; naloxone and/or other antidote(s) administered can confirm and treat. If cyanosis and low pulse oximetry (90%) are present, arterial co-oximetry should be performed to evaluate for methemoglobinemia.

After excluding hemoglobinopathies and drug-induced respiratory suppression, further evaluation may include white blood cell differential, bronchial-alveolar lavage, chest radiograph, and/or high-resolution computed tomography (HRCT). Eosinophilia on peripheral blood smear or bronchial-alveolar lavage may suggest a drug-induced eosinophilic pneumonia. HRCT can further characterize the pathology [162–164]. Some diagnoses require an echocardiography, right-heart catheterization, and/or biopsy for diagnosis or to exclude other diagnoses. Echocardiography can exclude left-sided congestive heart and evaluate for cardiac comorbidities. A list of drugs associated with respiratory disease is maintained online by the Department of Pulmonary and Intensive Care at a University Hospital in Dijon, France (www.pneumotox.com). Table 12 contains a list of ICU drugs associated with more than 50 reports of respiratory disease.

Drug-Induced Airway Dysfunction

Refer to allergic/hypersensitivity ADRs section within this chapter where drug-induced bronchospasm and angioedema are discussed in detail.

Drug-Induced Parenchymal and Interstitial Lung Disease (ILD)

Parenchymal lung disease includes many subtypes, but commonly associated ICU drugs include amiodarone, antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), and drugs of abuse (before ICU admission). Frequently encountered conditions include acute ILD, subacute ILD, eosinophilic pneumonia, diffuse alveolar damage, and ILD with a granulomatous component. Patients who previously received chemotherapy can have ADRs based on their previous outpatient treatment regimens. Many chemotherapeutic drugs are associated with ILD. For example, ILD is emerging as a class effect of tyrosine kinase inhibitors (TKIs), inhibiting oncologic drugs that inhibit the vascular endothelial growth factor (VEGF) receptor. Diffuse alveolar damage (DAD) may be the most common manifestation, although other etiologies occur [165].

Amiodarone-induced respiratory disease has a wide spectrum of manifestations that can develop acutely or after many years [166–168]. The elderly may have higher risk. Peak onset occurs after 6–12 months of therapy [169]. Higher doses may be associated with increased risk although toxicity can develop with any dose [167, 170]. Typical presentation includes malaise, cough, fever, and pleuritic chest pain, with imaging demonstrating patchy opacities and/or acute respiratory distress syndrome (ARDS). Sometimes only pulmonary fibrosis is present, but pathological manifestations can include eosinophilic pneumonia, bronchiolitis obliterans organizing pneumonia, or diffuse alveolar damage (DAD) [166]. DAD is a severe respiratory failure involving alveolar fibrin, hyaline membranes, reactive epithelial cells, and diffuse ground-glass opacities [166, 171]. If amiodarone-associated respiratory disease is suspected, the drug should be discontinued and alternative medications titrated to control heart rate.

Table 12 ICU drug-induced respiratory disease. Drugs from www.pneumotox.com were included if ≥ 50 cases reported for a drug–disease pattern. Pneumotox was referenced on May 17, 2015

Generic drug	Airway disease	Interstitial/parenchymal disease	Pleural disease	Pulmonary vasculopathy
Drugs of abuse (IV/inhaled)		Granulomatous ILD, mass(s), pneumoconiosis	PTX	PAH
Amiodarone		Acute/subacute ILD, PF, lung nodule(s), DAD	Fibrothorax, pleuritic chest pain	ARDS
Beta-2 agonists (parenteral)				NCPE
Beta-blockers	Bronchospasm			NCPE
Crack cocaine	Bronchospasm			
Dopamine agonists			Fibrothorax	
Ethanol				ARDS
Excipients (vehicle)				PAH
Hemotherapy (blood or platelet transfusion)				NCPE, ARDS, TRALI, TACO
Heroin (inhaled, insufflated, snorted)	Bronchospasm			
Heroin (injected)	Bronchospasm		PTX	NCPE, flash pulmonary edema
Hydrochlorothiazide				NCPE
Latex	Bronchospasm			
Minocycline		EP		
Nitrofurantoin		Acute pneumonitis/ILD, subacute pneumonitis/ILD, PF	Acute pleuritis	
NSAIDS	Bronchospasm	EP		
Salicylate	Bronchospasm			NCPE

Key: acute respiratory distress syndrome (*ARDS*), diffuse alveolar damage (*DAD*), dopamine (*DA*), eosinophilic pneumonia (*EP*), inhaled (*INH*), interstitial lung disease or pneumonitis (*ILD*), intravenous (*IV*), noncardiogenic pulmonary edema (*NCPE*), parenchymal lung disease (*PLD*), pneumothorax (*PTX*), pulmonary arterial hypertension (*PAH*), pulmonary fibrosis (*PF*), transfusion-associated circulatory overload (*TACO*), transfusion-related lung injury (*TRALI*)

Nitrofurantoin is associated with acute or subacute pneumonitis (ILD) characterized generally with bilateral and symmetric pulmonary opacities. Pulmonary fibrosis, eosinophilic pneumonia, or pleuropathy (discussed later) may be present with restrictive lung dysfunction and hypoxemia, which usually resolve after the drug is discontinued [172–174].

Eosinophilic pneumonias (EP) have been associated with a significant number of drugs; antibiotics and NSAIDS are the most commonly reported [175–184]. Historically, there have been epidemics of EP associated with exposure to a toxic-oil spill in 1981 and L-tryptophan ingestion in 1989. Minocycline was the antibiotic most

commonly reported by www.pneumotox.com (between 50 and 100 cases reported); daptomycin, nitrofurantoin, and sulfasalazine followed with 10–50 reported cases. The FDA has issued a warning regarding daptomycin and risk for eosinophilic pneumonia. Signs and symptoms of EP include fever, fatigue, dyspnea, wheezes with pulmonary infiltrates, and eosinophilia in blood, bronchial–alveolar lavage, and/or tissue [182]. Symptoms usually resolve after the implicated drug is discontinued; however, sometimes steroids are required.

ILD with a granulomatous component has been associated with drugs of abuse and mimics pulmonary and/or systemic sarcoidosis [185, 186].

The culprit could be a cutting agent such as levamisole or talc since the primary drug of abuse is more likely to cause other drug-induced respiratory disease (see Table 11). Heroin has been associated with bronchospasm, noncardiogenic pulmonary edema (NCPE), flash (fulminate) pulmonary edema, and/or pneumothorax [187, 188]. Crack cocaine has been associated with bronchospasm [189]. Other cutting agents such as clenbuterol, a beta-agonist, have been associated with NCPE [190], and topical anesthetics have been associated with methemoglobinemia [191]. Characteristically, ILD with a granulomatous component appears radiographically as sterile non-necrotizing granulomas and/or with a miliary appearance; lymphadenopathy may also be present [185, 186]. Patients may have granulomatous skin lesions.

Drug-Induced Pulmonary Edema and Vasculopathy

The lungs have an extensive vascular surface used for oxygenation and gas exchange, but this increases the risk for significant morbidity and mortality when endothelial and/or vascular injury occurs [192]. ARDS and noncardiogenic pulmonary edema (NCPE) are common clinical manifestations of drug-induced respiratory disease. Their clinical and radiographic features are difficult to distinguish from other causes of pulmonary edema; therefore, timing is an important consideration to determine etiology [193]. Patients may present with dyspnea, chest pain, tachypnea, and hypoxemia [193]. Chest imaging will demonstrate bilateral opacities not fully explained by effusions, atelectasis or nodules, and the absence of cardiomegaly and pulmonary vascular redistribution. Echocardiography or wedge pressure may be used to exclude cardiogenic causes, a requirement for the diagnosis of NCPE.

ARDS is defined and graded based on gas exchange abnormalities. The diagnosis is used interchangeably for mixed pathology but morphologically best characterized by DAD. ARDS is an acute, diffuse, inflammatory lung injury that increases pulmonary vascular permeability, hypoxemia, shunting, and pulmonary dead space. Using the Berlin definition, ARDS is defined

based on the degree of hypoxemia as mild ($\text{PaO}_2/\text{FIO}_2 \leq 300$ mmHg or $\text{P/F} \leq 300$), moderate ($100 < \text{P/F} \leq 200$), and severe ($\text{P/F} \leq 100$) [194]. Mortality increased for each stage, 27%, 32%, and 45%, respectively [194]. Duration of mechanical ventilation in survivors increased for each stage: 5, 7, and 9 days, respectively [194]. When an ADR is suspected, the drug should be immediately discontinued.

NCPE, or permeability edema, is associated with opioids [187, 188, 195–197]; the mechanism may involve histamine release with capillary leak [198]. These effects usually occur within hours of opioid use and may persist. Decreasing the doses of opioids and/or changing to less histaminergic opioids may be helpful. When pulmonary edema develops within minutes of drug administration, it is called flash (fulminate) pulmonary edema.

Transfusion-related acute lung injury (TRALI) is a type of drug-induced pulmonary edema associated with hemotherapy and should be differentiated from transfusion-associated circulatory overload (TACO). TRALI can occur with transfusion of blood, platelets, plasma, IVIG, or any blood product. TRALI has an incidence rate of 22.5 per 100,000 hospital stays; risk factors include continued platelet and plasma transfusions, amount transfused, female gender, white ethnicity, and 6-month histories of pulmonary fibrosis and/or tobacco use [199, 200]. Decreasing female donation of blood products significantly reduced the incidence but suggests there is both an immune and nonimmune mechanism [199, 201]. Symptoms of TRALI develop within 8 h of infusion and can be difficult to differentiate from TACO, a type of overload pulmonary edema. TACO can occur when the rate or amount of fluid infused is more than the circulatory system can accommodate. Assessing fluid balance and measurement of brain natriuretic peptide may suggest an etiology as TRALI and/or TACO [202].

Pulmonary Arterial Hypertension

Drugs increasing serotonin and/or norepinephrine levels may cause pulmonary arterial hypertension (PAH) because of the vasoconstrictive and growth-modulating effects on smooth muscle

cells, resulting in an increased pulmonary vascular resistance, right cardiac failure, and death. Another proposed mechanism includes endothelial dysfunction [203]. PAH associated with ICU drugs could occur through excipients (vehicle), as reported by Pneumotox. Other considerations include drugs of abuse such as amphetamines and cocaine, anorexic or appetite suppressants, and other over-the-counter drugs such as nasal decongestants [203–205]. Fenfluramine, an appetite suppressant, was withdrawn from the market and had been associated with PAH. Phenylpropanolamine, a nasal decongestant, was withdrawn because of an increased risk of hemorrhagic stroke and may have been a risk factor for PAH.

Drug-Induced Neuromuscular Respiratory Disease

Respiratory pump function is dependent on central respiratory drive, peripheral nerves, neuromuscular junctions, and respiratory muscles. Drug-induced neuromuscular respiratory disease is discussed in the neurologic ADR section.

Gastrointestinal ADRs

Drug-Induced Constipation/Ileus

Constipation is the irregular and/or infrequent evacuation of the bowels. Multiple causes have been identified including poor nutritional intake (low dietary fiber); emotional disturbances; systemic, structural, and infectious conditions; and drugs. Drug-induced constipation has been associated with drugs affecting muscarinic, opioid, and gamma-aminobutyric-acid (GABA) receptors. Opioids are the drug class most frequently associated with constipation, which occurs in up to 71% of patients with chronic non-cancer pain whom are prescribed with opioids [206].

Opioid-induced constipation has significant economic ramifications as it is associated with longer inpatient stays (3–5 days vs. 1–2 days) and higher costs (US\$16923–US\$23631 vs. US\$11117–US\$12652) [206]. For ICU patients, the costs could be even higher, and patients should be prescribed with bowel regimens to promote daily motility. When

conservative measures have failed, opioid antagonists may be considered (LoE_I). Cost is preclusive to widespread implementation. Naloxone, naltrexone, and nalmefene are opioid antagonists with low systemic bioavailability because of first-pass metabolism [61]. If given in sufficient doses, naloxone crosses the blood–brain barrier to reverse opioid analgesia; naloxone has a narrow therapeutic window when administered to treat opioid-induced constipation. Quaternary analogues of the opioid antagonists such as methylnaltrexone and alvimopan have greater polarity and lower lipid solubility; these analogues poorly cross the blood barrier. Methylnaltrexone is administered parenterally (0.15–0.3 mg/kg every other day) and alvimopan orally (0.5 or 1 mg once daily).

Delayed Absorption

Critically ill patients may already be at increased risk for delayed absorption of enteral medications. Some ICU drugs delay gastric emptying or slow motility and can interfere with the absorption of other drugs. Common drugs include anticholinergic, opioid agonists, anesthetics, and other sedatives. In the setting of overdose, absorption can continue longer than predicted by pharmacokinetics, especially for enteric coated or extended release medications, anticholinergics, and/or opioids [207–219].

Diarrhea

Many of the withdrawal states can be associated with diarrhea as can many antibiotics. Twenty-nine percent of 743 prospectively treated patients prescribed with inpatient antibiotics developed diarrhea during hospitalization, and four cases were confirmed of *Clostridium difficile* infection (CDI) [220]. Diarrhea started between 1 and 16 days after initiation with median onset on day 4. Potentially any antibiotic is associated with diarrhea, but cephalosporins, clindamycin, penicillins, and quinolones may carry a higher risk, especially for CDI [221]. Antibiotic-associated diarrhea was associated with increased age, proton pump inhibitor use, and being critically ill. The prevalence of CDI for ICU patients prescribed with antibiotics may be higher than other

Table 13 Clinical phenotypes for DILI associated with ICU drugs. Clinical phenotypes associated with ICU drugs with latency, initial bilirubin, and R value. R is calculated:

(ALT/ULN)/(ALP/ULN) (Source: <http://livertox.nlm.nih.gov> (Accessed 5/18/2015))

Clinical phenotype	Latency	Bilirubin (mg/dL)	R	Drugs
Acute hepatic necrosis	<2 weeks	<10	>5	Acetaminophen, amiodarone, aspirin, cocaine, methylenedioxymethamphetamine (MDMA, ecstasy), niacin
Acute hepatitis	2–24 weeks	>2.5	>5	Disulfiram, isoniazid (INH), nitrofurantoin, sulfonamides
Cholestatic hepatitis	2–12 weeks	>2.5	<2	Ceftriaxone, clavulanate, fluoroquinolones (ciprofloxacin, levofloxacin), macrolides, penicillins, rifampin, sulfonamides, sulfonylureas
Mixed hepatitis	4–24 weeks	>2.5	2–5	Aromatic antipsychotics (e.g., carbamazepine, phenytoin), lamotrigine, NSAIDs, sulfonamides

Abbreviations: alanine aminotransferase (ALT), alkaline phosphatase (ALP), bilirubin (BILI), upper limit of normal (ULN)

hospitalized patients and has been reported as 25% in patients with antibiotic-associated diarrhea [222]. CDI-associated mortality rate may be as high as 9% [223], and for ICU patients, the unadjusted rate may be as high as 23–37% [222, 224, 225]; however, other literature suggests early recognition and treatment of ICU-acquired CDI decreases the risk for mortality [226].

The development of antibiotic-induced diarrhea results in an additional hour of nursing care per day which decreases nurse time spent with other critically ill patients [220]. Patients who develop CDI have a longer length of stay of 2.2 ICU days, 4.5 hospital days [224]. Probiotics have been studied for the prevention of antibiotic-associated diarrhea and/or *Clostridium difficile* diarrhea; in older hospitalized patients, they may not be as helpful when compared to other age groups [227–229]. Decreasing hospital use of quinolones may decrease the overall incidence of *Clostridium difficile* [230–233]. Antimotility agents should be avoided until CDI is ruled out with a rapid screening ELISA test.

Drug-Induced Hepatotoxicity

This section briefly discusses ADRs associated with hepatotoxicity; for additional information refer to ► Chap. 17, “Toxicant-Induced Hepatic Injury.” Drug-induced liver injury (DILI) is the major reason for drug removal or restriction by regulatory agencies and is estimated to occur in 1 in 1,000,000 patient-years or 35 cases in 100,000 using EMR data [5, 234]. Fewer than

10% of DILI cases progress to drug-induced acute liver failure and up to 80% of these will die or require transplantation [235, 236].

DILI mimics many forms of liver disease and is usually a diagnosis of exclusion. Complicating the diagnosis is the latency period or the time from first dose of a new drug to the onset of hepatotoxicity. For hepatotoxic ADRs, the latency period is usually days to weeks after starting a new medication, but there are exceptions. The clinical signs and symptoms are usually nonspecific but temporally can be used to guide the differential. A good reference to published case reports is Livertox (<http://livertox.nlm.nih.gov>), which is continuously updated (Table 13) [234, 237]. Patterns of hepatic enzyme elevation can suggest hepatocellular, cholestatic, or mixed injury patterns (Table 14). These patterns of elevation also guide workup for alternative explanations (e.g., hepatocellular or mixed DILI should be tested for acute viral hepatitis, while a cholestatic pattern should be evaluated for biliary tract pathology).

The most common phenotype is serum enzyme elevation without jaundice or other symptoms. The most characteristic phenotype suggesting DILI is cholestatic and/or mixed hepatitis. Between 30% and 50% of DILI cases are described as acute hepatitis and resemble acute viral hepatitis. The most concerning phenotype is acute hepatic necrosis, characterized by many-fold elevations of ALT within days of drug exposure; however, the most likely phenotype to result in DIALF is acute hepatitis.

Table 14 Laboratory criteria for diagnosing and classifying drug-induced liver injury (DILI). DILI can be diagnosed when either ALT or ALP is elevated or when both

BILI and ALT are elevated. R is calculated (ALT/ULN)/(ALP/ULN) and patterned based on earliest identified liver chemistry available that qualifies as DILI

DILI diagnosis	ALT $\geq 5 \times$ ULN	ALP $\geq 2 \times$ ULN	Bilirubin $\geq 2 \times$ ULN and ALT $\geq 3 \times$ ULN
DILI classification	R		
Hepatocellular	≥ 5		
Mixed	$2 < R < 5$		
Cholestatic	≤ 2		

Abbreviations: alanine aminotransferase (ALT), alkaline phosphatase (ALP), upper limit of normal (ULN)

Drug properties and certain host factors increase risk for DILI. High lipophilicity ($\text{LogP} \geq 3$) and high daily dose (≥ 100 mg) predict DILI [238]. Patients with fatal outcomes are more likely to have chronic liver disease and satisfy Hy’s Law (ALT or AST $> 3 \times$ ULN and bilirubin $> 2 \times$ ULN with no initial findings of elevated serum ALP or other reason for abnormal liver biochemistries) [239]. Mechanisms for DILI include the formation of toxic metabolites (e.g., *N*-acetyl-*p*-benzoquinone imine from metabolism of acetaminophen), mitochondrial dysfunction [240], modification of allergic mediators [242] and altered bile acid homeostasis [241]. Minocycline can induce an allergic or autoimmune injury with antinuclear antibodies (ANA) and perinuclear antineutrophil cytoplasmic antibodies, pANCA. Nitrofurantoin autoimmune hepatitis is associated with antinuclear and smooth muscle antibodies [243, 244]. DILI associated with amoxicillin–clavulanate has been associated with the HLA alleles A*02:01, DRB1*15:01-DQB1*06:02 [245]. Some drugs may cause DILI through hypotension and/or increased metabolic demand. Drugs that can cause hypoxia or hypotension, or increase metabolic demands, may worsen acute liver failure because each of these conditions by itself can cause ALF.

Causality can be difficult to determine, but the suspected drug(s) should be immediately discontinued and the liver biochemistries monitored; the liver has an amazing capacity to recover from injury [246]. Rechallenge is dangerous and should be avoided. Currently available biomarkers [247–252] (Table 15) are not specific enough and/or not widely available; a liver biopsy should be considered if signs of liver function

continue to decline or if peak ALT level has not fallen by $> 50\%$ at 30–60 or 180 days, respectively, for hepatocellular and cholestatic DILI [253]. Exceptions, or drugs to consider restarting, may include an immunomodulatory drug if no alternatives are available.

Drug-Induced Pancreatitis

Acute pancreatitis is a sudden inflammation of the pancreas and can be fatal; however, drug-induced acute pancreatitis is usually mild or moderate in intensity. The most commonly identified cause of acute pancreatitis is gallstone followed by ethanol, drugs, and cannabis [254]. Drug-induced acute pancreatitis (DIAP) occurs for less than 5% of patients with acute pancreatitis, and drugs with stronger causality are listed in Table 16 [255, 256]. Mechanisms for DIAP include pancreatic duct constriction, cytotoxic and metabolic effects, accumulation of a toxic metabolite, or intermediary and/or hypersensitivity reactions [257, 258].

There are many drugs possibly associated with pancreatitis but causality is not definitively established. There have been numerous reports of adverse effects with drugs such as the antipsychotics clozapine, olanzapine, and risperidone, but when a cause–effect relationship is scrutinized, the data is questionable [10, 259]. For glucagon-like peptide-1 drugs such as exenatide, pancreatitis was seen in the clinical trials but other studies have demonstrated mixed results [260]. Class labeling warnings have been added to the FDA labels. ICU drugs associated with acute pancreatitis with stronger causality (positive rechallenge and other causes excluded) include ace inhibitors (ACEI; enalapril), antiepileptics (divalproate), antimicrobials (dapstone,

Table 15 Liver biochemical and function tests. Most of these biomarkers are located intracellularly and released after hepatocyte injury

Biomarker	Clinical significance
Hepatocellular injury	
ALT	Remains elevated longer than AST (longer half-life)
AST	Less specific than ALT
APAP-CYS	Early and specific marker for APAP hepatotoxicity; remains elevated for days
GSTA	Centrilobular injury; more rapid assessment because of shorter half-life than ALT/AST
HMGB1	Associated with immune activation followed by apoptotic and necrotic hepatocytes; earlier marker of hepatotoxicity than ALT; prognostic marker
K18	Necrotic hepatocytes; prognostic marker
K18, cleaved	Apoptotic hepatocytes; prognostic marker
miR-122	Earlier marker of hepatotoxicity than ALT; can be used to predict injury
SDH	Earlier marker of hepatotoxicity than ALT
Biliary injury	
ALP	Nonspecific and can be elevated with bile duct obstruction, cholestasis, and hepatocellular injury as well as released from bone and placental tissue
GGT	More sensitive and specific marker of biliary injury than ALP
Mitochondrial injury	
GLDH	Earlier marker of hepatotoxicity than ALT, released from mitochondria
Hepatic biosynthetic capacity	
Albumin	Produced by the liver and decreased in chronic liver disease; decreased in nephrotic syndrome
Ammonia	Released by intestines and metabolized by liver
PT	Decreased production of hepatic coagulation factors increases PT
Hepatic regeneration	
AFP	May have value as prognostic marker
LECT2	May have value as prognostic marker; inversely proportional to ALT

Abbreviations: acetaminophen (*APAP*), acetaminophen–cysteine adducts (*APAP-CYS*), alanine aminotransferase (*ALT*), alkaline phosphatase (*ALP*), alpha-fetoprotein (*AFP*), alpha-glutathione-S-transferase (*GSTA*), aspartate aminotransferase (*AST*), gamma glutamyl-transpeptidase (*GGT*), glutamate dehydrogenase (*GLDH*), high-mobility group box-1 (*HMGB1*), keratin 18 full length (*K18*), leukocyte cell-derived chemotaxin-2 (*LECT2*), microRNA-122 (*MiR-122*), prothrombin time (protime, *PT*), sorbitol dehydrogenase (*SDH*)

metronidazole, tetracycline), cannabis, diuretics (furosemide), and statins (pravastatin, simvastatin) [256]. Drugs with positive rechallenge but without other causes excluded include amiodarone, antimicrobials (sulfamethoxazole/tazobactam), ARBs (losartan), and proton pump inhibitors (omeprazole) [256]. ICU drugs with more than four case reports of acute pancreatitis include acetaminophen, erythromycin, and propofol [256].

The proposed mechanism for pancreatitis caused by statins is via accumulation of a toxic metabolite or drug interactions through cytochrome P450 3A4 [261]. Valproic acid may cause pancreatitis by a direct toxic effect of free

radicals and depletion of superoxide dismutase, catalase, and glutathione peroxidase [261]. When drug-induced pancreatitis is suspected, the implicated agent should be discontinued [255].

Renal ADRs

Drug-Induced Acute Renal Failure

This section discusses ADRs associated with acute renal failure. For additional details, refer to ► [Chap. 18, “Toxicant-Induced Renal Injury.”](#) Drugs are a common cause of renal insufficiency because a major route for drug excretion occurs

Table 16 Drug-induced pancreatitis. Drugs are grouped by drug class and listed when stronger causality has been documented

Class	Drug(s)
ACEI/ARBs	Enalapril and losartan
Antiarrhythmics	Amiodarone
Antiepileptics	Divalproate
Antimicrobials	Dapsone, metronidazole, sulfamethoxazole/tazobactam, and tetracycline
Cannabis	
Diuretics	Furosemide
Ethanol	
Glucagon-like peptide-1 (GLP1) receptor agonists	Exenatide, liraglutide, albiglutide, dulaglutide
Proton pump inhibitors	Omeprazole
Statins	Pravastatin and simvastatin

renally. During this process, drugs concentrate in nephric tissues which increase the potential for local tissue toxicity [262]. The high renal rate of blood flow increases nephric tissue exposure to drugs when compared to tissue in organs with lower rates of blood flow.

Drug-induced nephrotoxicity should be considered when the serum concentration of creatinine rises temporally in relation to drug administration. Good ICU care noting a diminishing urine output should avoid this complication. Drug toxicity in the kidney can manifest through the same clinical syndromes associated with other kidney diseases (refer to Table 17 for common clinical syndromes matched with associated drugs). Antibiotics are the most common cause of drug-induced renal failure; aminoglycosides are the most common cause of acute tubular necrosis (ATN), with an incidence of at least 10% of all cases of acute renal failure [263]. Penicillins and sulfonamides are more commonly associated with acute interstitial nephritis (AIN). Some drugs such as cephalosporins, cocaine, and NSAIDs can be associated with multiple renal syndromes [264–267]. When considering drug-induced nephrotoxicity, consider the dose, timing, duration of exposure, concurrent use of nephrotoxic drugs, and individual patient

Table 17 Nephrotoxicity associated with ICU drugs

Clinical syndrome	Drug
Acute renal failure	
Prerenal/hemodynamic	Contrast, amphotericin B, ACEI, NSAIDs
Intrarenal	
ATN	Acetaminophen, aminoglycosides, amphotericin B, cephalosporins, cocaine
AIN	Penicillins, cephalosporins, cocaine, sulfonamides, NSAIDs
Postrenal/obstructive	Acyclovir, analgesic abuse
Nephrotic syndrome	NSAIDs
Chronic renal failure	Lithium, analgesic abuse

Abbreviations: acute tubular necrosis (ATN), acute interstitial nephritis (AIN)

risk factors (age, chronic kidney disease, sepsis, etc.) [262, 263, 268–271].

Prerenal Nephrotoxicity

Prerenal azotemia is a hemodynamically mediated renal insufficiency associated with low urine sodium excretion and is usually reversible when the offending agent is discontinued early. Some drugs, such as radiocontrast agents, cause vasoconstriction through increased production of endothelin and/or thromboxane A2 which reduces renal blood flow and glomerular perfusion [272]. Radiocontrast agents can impair renal blood flow by both vasodilation and vasoconstriction; contrast nephropathy usually develops within 24 h after administration [272]. Risk factors include preexisting renal impairment, severe congestive heart failure, volume depletion, age, dose, and concurrent use of other nephrotoxins; there was no statistical difference in the complication rate when changing the type of contrast prescribed (high/low osmolality or ionic/non-ionic) [272, 273].

NSAIDs inhibit cyclooxygenase and decrease the synthesis of vasodilating prostaglandins, which in patients with chronic renal disease can impair glomerular perfusion [270, 274]. ACEIs

inhibit the conversion of angiotensin I to II; angiotensin II is a potent vasoconstrictor which helps to maintain glomerular perfusion at the efferent arteriole when renal blood flow is compromised [274]. Azotemia initially occurred for 25% of patients receiving vancomycin, but when the impurities were addressed, the incidence of nephrotoxicity decreased to less than 7% and was associated with a significantly elevated vancomycin trough [275].

Intrarenal Nephrotoxicity

Drug-induced nephrotoxicity from intrarenal mechanisms occurs through ATN or AIN [262, 265, 276]. ATN is often a result of direct drug toxicity on the renal tubular cells; the urinalysis can demonstrate proteinuria, tubular epithelial cells, and noncellular casts. ATN outcomes may be predicted based on the number of cells and casts visualized on the urinalysis [277]. Aminoglycosides accumulate within the renal cortex tubular cells with nephrotoxicity occurring 5–7 days into the antibiotic course; rank order for nephrotoxicity from greatest to least includes gentamicin, amikacin, and tobramycin [278]. Acetaminophen has been associated with ATN with therapeutic doses or following overdose [279–281]. Cephalosporins can cause ATN and/or AIN; a rank order for potential tubular toxicity from animal studies suggests cephazolin has increased risk compared to cephalexin and ceftazidime [276, 282, 283]. AIN is a result of intrarenal inflammation and often has systemic signs of hypersensitivity such as fever or rash; urinalysis can contain proteinuria, red and/or white cells, and/or cellular casts [265].

Postrenal Nephrotoxicity and Nephrotic Syndrome

Postrenal or obstructive nephrotoxicity associated with ICU drugs can occur when insoluble drugs such as acyclovir precipitate into the renal tubular lumen [284]. Acyclovir has been associated with nephrotoxicity when administered intravenously and at high doses [284]. Urine sediment can contain red and/or white cells with needle-shaped birefringent crystals. Drug-induced nephrotic syndrome has occurred with NSAIDs and is

diagnosed when proteinuria, hypoalbuminemia, and edema are present [266, 285–287].

Treatment

Modalities such as therapeutic drug monitoring programs may decrease risk for nephrotoxicity [288]. Drugs such as vancomycin and gentamicin can be monitored with trough and/or peak blood concentrations; risk for nephrotoxicity is avoided with shorter courses of treatment and the use of the lowest effective drug concentration [275, 278]. Once nephrotoxicity has occurred, treatment is based on identifying potential nephrotoxins and avoidance of concurrent use of other nephrotoxic drugs [274, 289]. Intravenous hydration is beneficial in some circumstances, as are diuretics [271]. After the nephrotoxicity has resolved, the drug can be resumed with renal dosing in some circumstances, but in the setting of nephrotic syndrome or AIN, the drug should not be restarted.

Neurologic ADRs

Drug-Induced Delirium

This section discusses ADRs associated with delirium. For additional reference, see ► Chap. 19, “Toxicant-Induced Alterations in Consciousness.” ICU delirium has been referred to as ICU psychosis, acute brain dysfunction or failure, and acute encephalopathy, among other terms. ICU delirium can prolong mechanical ventilation and is associated with a threefold higher rate of re-intubation, an increased rate of ventilator-associated infections, prolonged hospital stays, and increased 1-year mortality [290, 291]. Delirium is defined as a fluctuating change in attention, cognition, consciousness, and/or perception and can be further categorized as hyperactive, hypoactive, and mixed [290, 292]. Vanderbilt University Medical Center maintains the website www.icudelirium.org as a resource for delirium and includes screening and management tools for emergency department, ICU and non-ICU patients. When assessing delirium, workup for toxicologic or pharmacologic causes should occur simultaneously with

Table 18 ICU drugs associated with delirium by class. ICU delirium can prolong mechanical ventilation and is associated with increased risk of infection, prolonged hospital stay, and 1-year mortality. Workup for toxicologic or pharmacologic causes should occur simultaneously with evaluation for other causes as delirium is often multifactorial. Some conditions not normally associated with delirium when occurring concurrently with other pathologies

Class	Generic name	Mechanism
Analgesic – opioid	Fentanyl	5HT, kappa-opioid agonist
	Meperidine	5HT, MAOI
	Hydromorphone	kappa-opioid agonist
Analgesic – dissociative hypnotic	Cyclohexanone–ketamine	NMDA antagonist
Antibiotic – aminoglycoside	Gentamicin	NMDA agonist, decrease ACh release and effect. Iron complexes inhibit mitochondria resulting in lipid peroxidation
Antibiotic – penicillins	Penicillin	GABA-A antagonism
Antibiotic – cephalosporin	Cefepime	GABA-A antagonism
Antibiotic – carbapenem	Imipenem	GABA-A antagonism
Antibiotic – fluoroquinolones	Moxifloxacin or levofloxacin	GABA-A antagonism and NMDA agonist
Antibiotic – oxazolidinones	Linezolid	MAOI
Anticholinergics	Some antiemetics, antihistamines, antipsychotics, and muscle relaxants	Muscarinic acetylcholine antagonist
Antiemetics	Diphenhydramine	Muscarinic acetylcholine antagonist
Antipsychotics	Haloperidol	Dopamine antagonism
	Olanzapine or quetiapine	Muscarinic acetylcholine antagonist
Benzodiazepines	Midazolam or lorazepam	GABA-A agonist
Corticosteroids	Solumedrol	Disturbances in the hypothalamo–pituitary–adrenal axis

Abbreviations: gamma-aminobutyric acid (GABA), monoamine oxidase inhibitor (MAOI), serotonin (5HT)

evaluation for other causes as delirium is often multifactorial [293]. Table 18 discusses drugs associated with delirium by class.

Consider the timing and progression of neurological symptoms in relation to all prescribed hospital drugs. Consider previous medications (prescribed or non-prescribed) that have been abruptly discontinued and their propensity to cause withdrawal (for additional information, refer to ► Chap. 27, “Withdrawal Syndromes”). Certain withdrawal states not normally associated with delirium, when occurring concurrently with certain pathologies, may be

may be considered. Consider drug or withdrawal states resulting in disturbances in the production, release, and/or effects of acetylcholine, endorphins, GABA, glutamate, 5HT, and dopamine neurotransmitters. Substance-induced psychosis is associated with the longer duration use of alcohol, amphetamines, cannabimimetic agonists, cocaine, and hallucinogens. Drug withdrawal delirium occurs classically with alcohol, benzodiazepine, and barbiturates

considered. Examples include nicotine, opioid, and cannabis withdrawal. Nicotine withdrawal in the setting of brain injury has been associated with delirium [294]; however, larger review studies have not clearly implicated nicotine withdrawal with delirium in hospitalized patients [295]. Opioid withdrawal is not normally associated with delirium but in the ICU should be considered as a contributor, as opioid withdrawal can occur after only 5 days of continuous opioid analgesia and by day 9 occurred in 100% of patients [296]. Cannabis withdrawal is associated with anger, aggression, and

irritability; performing urine drug screens at admission could help to identify patients at risk since this is the most common illicit drug used in the USA and withdrawal symptoms can persist for 3 or more weeks [297–301]. Synthetic cannabinoid withdrawal has been reported, but the propensity for delirium is not yet clear [302].

Consider previous medications (prescribed or non-prescribed) that may interact with currently prescribed ICU drugs; commonly implicated drugs include serotonergic, anticholinergic, and *N*-methyl-D-aspartate (NMDA) receptor antagonists [303–305]. Previous substance misuse should be considered, especially for dopaminergic drugs, as these drugs are associated with substance-induced psychosis and may be a function of the severity of use and dependence and persist for months after last use. Drugs implicated include alcohol, amphetamines, cannabimimetic agonists, cocaine, hallucinogens (e.g., methylenedioxymethamphetamine MDMA), and NMDA antagonists (e.g., phencyclidine and ketamine) [306]. Independent precipitating factors for delirium such as bladder catheters, fecal management systems, immobilizing therapies, and restraints should be avoided [290, 307, 308]. Major groups of ICU drugs associated with delirium that may be evaluated by a medical toxicologist include analgesics, antibiotics, antipsychotics, and sedative-hypnotics.

Analgesics

Analgesic-induced delirium could occur by interaction with other medications, opioids with serotonergic properties, and/or kappa-opioid agonism [309]. Fentanyl and/or methadone may interact with linezolid or other monoamine oxidase inhibitors (MAOI) or serotonergic medication resulting in serotonin syndrome [310–316]. A retrospective review of 4538 patients treated with fentanyl and concurrent serotonergic agents suggests the incidence of serotonin syndrome was low [311], but prospective studies are needed before ignoring this ADR as there are many case reports suggesting a higher incidence [310–312, 317–322].

Furthermore, the hospital stay and mortality among patients prescribed with serotonin

reuptake inhibitors prior to ICU admission are higher and may be related to an analgesic reaction [323]. Serotonin reuptake inhibitors may also increase risks secondary to platelet serotonin inhibition and increased bleeding risk or other mechanisms [324–328]. Propensity for kappa-opioid agonism may be another factor to consider when evaluating delirium after opioid administration; fentanyl and hydromorphone may have higher risk in animal studies [309].

When delirium is suspected to be drug mediated, the implicated drug(s) should be discontinued. If opioid-induced delirium is suspected, opioid avoidance or lower doses are recommended by one large prospective study [329]. If a patient has a history of prescription or illicit serotonergic substance use, consider avoiding serotonergic drugs such as fentanyl until more prospective data is available. For opioid withdrawal, initiating a long-acting full or partial opioid agonist may be best until the patient has been extubated and then further tapered and/or provided with symptomatic treatment.

Antibiotics

Major groups of antibiotics associated with delirium include aminoglycosides, beta-lactams (penicillins, cephalosporins, and carbapenems), fluoroquinolones, oxazolidinones (linezolid), and trimethoprim/sulfamethoxazole. Aminoglycosides activate NMDA receptors, inhibit presynaptic release of acetylcholine, and bind postsynaptic receptors. Chronic toxicity (increased trough levels) occurs when iron complexes inhibit mitochondria and cause lipid peroxidation. Aminoglycosides are associated with peripheral neuropathy and neuromuscular blockade; case reports have linked gentamicin to encephalopathy [330] (Table 19).

The beta-lactam ring itself is known to be neurotoxic and drugs containing this structure cause neurotoxicity by GABA-A antagonism. For beta-lactams, symptoms of neurotoxicity usually present 12–72 h after initial administration, but can occur later after increased dosing or when metabolic and/or elimination pathways are inhibited. Previous case reports have identified the following risk factors: being critically ill,

Table 19 Major antibiotic classes associated with neurotoxicity. The beta-lactam ring is epileptogenic with variability depending on side chains and other substitutions

Drug or class	Mechanism	Onset	Signs/symptoms
Penicillins and cephalosporins	Inhibit GABA binding to GABA-A receptor, blocks GABA-A chloride channel	12–72 h	Confusion, dysarthria/aphasia, agitation, lethargy/coma, myoclonus, seizures, and/or NCSE
Carbapenems	Affinity for GABA-A receptor complex	3–7 days	Focal and generalized seizures
Fluoroquinolones	Inhibit GABA binding to GABA-A receptor, NMDA agonist	1–4 days	brief tonic–clonic, sustained generalized myoclonus
Isoniazid	Inhibit pyridoxine kinase	30 min–2 h	Recurrent, generalized tonic–clonic seizures
Metronidazole	Increased hydroxy and 1-acetic acid metabolites	5–7 days	Seizures, peripheral neuropathy

Abbreviations: gamma-aminobutyric acid (*GABA*), nonconvulsive status epilepticus (*NCSE*)

reduced creatinine clearance, preexisting CNS conditions and/or damage to the blood–brain barrier, concurrent use of other neurotoxic drugs, and dosing errors [330–335]. Symptoms of beta-lactam neurotoxicity are secondary to impaired GABA-A transmission [335]. Cephalosporins with higher affinity for GABA-A receptors and those with higher CNS penetrance are more neurotoxic. Resulting clinical effects range from coma to agitation and can fluctuate with delirium, aphasia, myoclonus, seizures, and nonconvulsive status epilepticus. Cefazolin, cefepime, and ceftazidime may have higher risk for neurotoxicity, while cephalexin and ceftriaxone may be lower. A retrospective review of 100 patients prescribed with cefepime found the incidence of encephalopathy was 15% [336].

Fluoroquinolone's mechanism of toxicity includes inhibition of GABA-A receptors and activation of NMDA receptors. CNS reactions occurred for 3% of patients prescribed with gemifloxacin, but other quinolone derivatives implicated include gatifloxacin, moxifloxacin, ofloxacin, and, its levo-stereoisomer, levofloxacin. Neurotoxicity can be manifested as delirium associated with psychotic features including delusions and hallucinations as well as restlessness and seizures.

Antipsychotics

Literature suggests that quetiapine decreases the incidence of ICU delirium although other antipsychotics can be used to effectively treat ICU

delirium after it has occurred [337–340] (LoE 1). As with the initiation of any medication, the antipsychotic side-effect profile should be considered when prescribing an antipsychotic for delirium; haloperidol may be associated with extrapyramidal symptoms, while olanzapine was found to be the most sedating [341]. Combining the critical care and toxicology literature, antipsychotics with anticholinergic properties should be used at low doses when treating delirium not suspected to be anticholinergic; some antipsychotics such as olanzapine and quetiapine cause agitation because of anticholinergic mechanism. Anticholinergic toxicity from olanzapine and/or quetiapine (or any other anticholinergic medication) can be diagnosed and treated with appropriately dosed physostigmine [342–344].

Benzodiazepines

Benzodiazepine use increases the risk of delirium [308, 345–347]. This could be through a paradoxical reaction, after prolonged ICU use, or benzodiazepine withdrawal [348]. If benzodiazepine delirium is suspected, appropriately dosed flumazenil can diagnose and treat patients following intubation or after benzodiazepine overuse and following alcohol withdrawal with little if any risk for seizures or precipitating withdrawal [346, 349–355]. Historically, patients with benzodiazepine dependence has been used as a contraindication to flumazenil, and a meta-analysis warns against the use of flumazenil, but when patients who received an initial flumazenil dose

of 1 mg or more were excluded, there were no significant adverse events in either the placebo or flumazenil groups [356]. Benzodiazepine dependence is not an absolute contraindication to flumazenil (LoE II-1). Flumazenil, therefore, should be dosed at 0.2–0.3 mg if there are concerns about rapid awakening or, otherwise, 0.5 mg; if improvement is observed, discontinue benzodiazepines and repeat flumazenil as needed when symptoms recur (LoE II-1) [346]. If benzodiazepine withdrawal is suspected, replace with a longer-acting benzodiazepine such as diazepam or with phenobarbital (LoE III) [357]. Another option for patients at risk for benzodiazepine withdrawal is a phenobarbital taper [358]; this may be beneficial for patients who received benzodiazepines with extended duration while mechanically ventilated.

Steroids

Neuropsychiatric effects including agitation occur in about 6% of patients who receive steroids; dose is the most significant risk factor [359]. ICU patients may experience agitation, delirium, and/or failure to wean [360–364]. Treatment includes reducing or avoiding steroids; however, some studies have suggested steroid switching (LoE III) and treatment with antipsychotics such as risperidone [360, 362, 365–369] (LoE III).

Disturbances in Circadian Rhythm

ICU delirium is often multifactorial, and disturbances in circadian rhythm and sleep deprivation can contribute to hypoxia, infectious, metabolic, and ADRs. Risk factors may include age and existing dementia or cognitive impairment. Circadian rhythm disturbance is a diagnosis of exclusion. Melatonin can be used to facilitate circadian rhythm and can decrease need for sedation improving neurologic indicators although further study is needed [370, 371] (LoE I).

Treatment

Pharmacologic sedation should be titrated to the least effective dose with at least daily sedation holidays to minimize the incidence of delirium. Avoiding infusions is one method for titrating sedation to the least effective dose. Once delirium

has occurred, treatment is based on identifying and discontinuing potential causative medications. Consider previous medications (prescribed or non-prescribed) that have been abruptly discontinued and their propensity to cause withdrawal. Also, consider previous medications (prescribed or non-prescribed) that may interact with currently prescribed ICU drugs.

If benzodiazepine or anticholinergic delirium is high on the differential, flumazenil and/or physostigmine can be administered safely; positive results may avoid costly and unnecessary radiographic testing that place the patient at increased risk for morbidity and mortality (e.g., during transport and while outside of the ICU setting [372]). If opioid withdrawal is a suspected contributor, the administration of a long-acting opioid will ameliorate the delirium. The patient can later be treated symptomatically for opioid withdrawal if not a candidate for outpatient opioid maintenance therapy.

Dexmedetomidine is an imidazole alpha-2 agonist that increases days alive without delirium or coma while in the ICU when compared to lorazepam [373]. The incidence of delirium was 54% in dexmedetomidine vs 77% in midazolam-treated patients ($P < 0.001$). There was no significant difference in time at targeted sedation level for 375 patients located in 68 centers in five countries who were treated in a double-blind, randomized trial [374]. Dexmedetomidine has caused hypotension during the initial bolus in between 25% and 56% of patients and, compared to benzodiazepines, may be more likely to cause bradycardia, which is the most significant ADR [373, 374]. Since dexmedetomidine is not usually associated with respiratory depression, it can be used to treat withdrawal syndromes in non-ventilated patients [374–376]. Cost is a consideration when considering dexmedetomidine; compared to midazolam, dexmedetomidine lowered total ICU costs and decreased ventilator time and ICU length of stay [377]. However, for moderate to severe anticholinergic delirium, physostigmine would be expected to be a more cost-effective primary therapy; dexmedetomidine could be used as an adjunct to avoid higher doses of benzodiazepines, but additional studies are needed.

An alternative to dexmedetomidine for pharmacies who restrict its use may be clonidine, and one study proposed the use of a short course of dexmedetomidine before transitioning to sublingual or orally administered clonidine [378]. The mechanism of these drugs differs such that the ratio of alpha-1 to alpha-2 may predispose clonidine to more hypotension and bradycardia and less sedation compared to dexmedetomidine, but the cost savings are difficult to ignore.

Drug-Induced Seizures

This section discusses ADRs associated with seizures. For additional details refer to ► Chap. 20, “Toxicant-Induced Seizures.” Six percent of new-onset seizures and 9% of status epilepsy may be drug related [379]. Major classes of drugs associated with seizures include antidepressants, anticholinergics/antihistamines, and stimulants, but the clinician should also consider NSAIDs, beta-lactams, quinolones, and drug withdrawal [336, 380–385]. Consider drugs previously prescribed that have not been continued in the ICU such as baclofen, gabapentin, pregabalin, zolpidem, and zopiclone; any drug acting at the GABA complex should be considered [386–391]. ICU drugs cause seizures by inadequate inhibitory neurotransmitters (e.g., GABA), excessive excitatory neurotransmitters (e.g., glutamate), and/or interfering with sodium channels [385, 392]. Antimicrobials impair GABA-A transmission [335, 393]. Magnesium homeostasis may be associated with seizures as diuretics, proton pump inhibitor, and antimicrobials may decrease the seizure threshold [335, 393].

Seizures are treated with either benzodiazepines or barbiturates; generally barbiturates are considered to be a second-line therapy [385]. Antiepileptics are ineffective when the mechanism of toxicity is caused by metabolic abnormalities or drugs impairing GABA-A transmission. Antiepileptics could be considered if seizures persist despite first- and second-line treatment.

Strategies to Decrease ICU ADRs

Patients admitted to the ICU have a higher mortality compared to hospitalized patients; 30-day mortality ranges from 12% to 44% depending on

the ICU patient subtype [394]. Thirty-four to forty-five percent of ADRs are preventable and represent an opportunity for risk reduction and improved patient safety [5, 7, 395]. Prior studies have demonstrated that technology, multispecialty care teams, specialized treatment centers, and standardized treatment algorithms can assist with these goals.

Technology has facilitated the development of medication databases and systems to identify potential drug–drug interactions, and one study identified that 11% of ICU admissions have potential drug–drug interactions [396]. As with any technology with an alarm, there is potential for alarm fatigue and technology should be curtailed to the ICU population to minimize this [397]. Conversely, when an ICU ADR has been identified, technology can be used to identify medications potentially causing the condition, medications to avoid, and the appropriate medications to use.

Multispecialty care teams consist of admitting physicians, consulting physicians, pharmacists, nurses, specialty therapists, care coordinators, and social workers. In the ICU, the value of the pharmacist is especially important. Pharmacists obtain medication histories; develop and manage policies and protocols for optimal patient care, drug expenditures, and cost avoidance (i.e., analgesia, anticoagulation, delirium, pharmacokinetic, sedation, and transfusion guidelines); optimize antimicrobial stewardship; respond to resuscitation events; verify accuracy of computerized order entry; educate other ICU personnel; assist in discussing treatment modalities with patients and/or families; prospectively evaluate drug therapy; and monitor and identify ADRs [398–410]. The impact of the clinical pharmacist in the ICU has significantly decreased ADRs, antimicrobial resistance, medication costs, transfusions, hemorrhage, ventilator days, and length of stay. Unfortunately, pharmacist services are not directly reimbursable; pharmacy departments receive funds from a hospital’s general operating budget. Pharmacy departments are penalized when they increase the ratio of clinical pharmacists to occupied beds from 1/100 to 1/20, an increased expenditure which was shown to

decrease ADRs by 48% [410]. The optimal pharmacist to patient ratio is unclear, but considering the services of a medical toxicologist are reimbursable, could a medical toxicologist enable a group of clinical pharmacists, thereby increasing the reimbursement of the pharmacy? Medical toxicologists, when available, are experts in pharmacokinetics and toxicokinetics and should develop relationships with multidisciplinary teams to aid in the reduction of the incidence of ADRs, length of stay, and mortality.

In addition to pharmacist to patient ratio and their impact on ADRs and mortality, patient to physician and/or nurse ratios should be considered. When nurse to patient ratio was greater than 2.5, the risk of death increased by 3.5. When the physician to ICU patient ratio exceeded 14, the risk of death increased by two [411]. High patient turnover and a high volume of life-sustaining procedures were also predictive of increased mortality. Admissions during weekday rounds did not increase mortality [412]. High-intensity daytime staffing reduced mortality [413].

Specialized treatment centers have been shown to improve care, especially for ICUs. Medical toxicology admitting services are not widely available, but there is great need as demonstrated by one large study of 3581 patients cared for primarily by toxicologists and non-toxicologists within the same hospital system as well as a third group of patients cared for by non-toxicologists outside of the hospital system. During the 2-year study period, there was a median savings of 1483 hospital days and \$4.3 million dollars, as well as a significant decrease in mortality for patients cared for by toxicologists [414]. Extrapolating from other specialty data, when only specialists are allowed to admit and care for critically ill patients, length of stay and mortality in the ICU were shortened [413, 415]. All things considered, patients cared for by non-specialists have increased risk for extended length of stay and mortality, which suggests that medical toxicologists and critical care intensivists should remain involved in patient care potentially until hospital

discharge. On admission, general recommendations may include holding any nonessential medication potentially resulting in drug–drug or disease–drug interactions; for example, many ICU patients may be started on antimicrobials, calcium channel blockers, and/or amiodarone, and these drugs increase concentration of simvastatin by inhibiting CYP3A4, thereby increasing drug levels resulting in an increased risk for rhabdomyolysis, renal failure, and hepatotoxicity [416–424]. Medical toxicologists may also provide daily recommendations for restarting or modifying home medications, as well as querying potential medication interactions, substance use disorders, and drug withdrawal. Until there are more admitting toxicology physicians, consultants should provide daily recommendations directly to the care team until the day of patient discharge. Interactive audio–video telemedicine consultation may be an alternative when traditional bedside care is not possible as this service has been useful for other specialties [425].

The ICU Setting	742
Epidemiology	742
Medication Use Process	743
Prevention Strategies	743
Drug–Drug Interactions	745
References	746

Medical errors and medication errors may cause patient harm and death and occur in all steps of the medication process and in all settings across healthcare. Some settings, such as the intensive care unit (ICU), involve higher risk of harm from such errors. This increased risk is due to many factors. Sicker patients with organ system(s) dysfunction and use of high-alert medications are two important factors for the risk of medication errors. Other risk factors such as age and comorbidities may also contribute. According to the Institute for Safe Medication Practices, a high-alert medication is “a drug that bears a heightened risk of patient harm when used in error” [1]. Medical toxicologists are sometimes consulted when a medication error occurs to provide expertise in management, to recommend treatment if necessary, and to offer mitigation strategies.

A medication error is defined as “any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer” [2]. An error can result in harm or may be intercepted prior to reaching the patient causing no harm (near miss). The medication use process, with functions such as prescription, transcription, dispensing, administration, and monitoring, lends itself to errors as each function can be broken into additional steps. Numerous strategies have been developed to mitigate errors at each of these functions to reduce harm to patients.

This chapter will provide an overview and explore the epidemiology of medication errors and drug–drug interactions in the ICU. Factors that lend themselves to causing errors and prevention strategies for errors will also be discussed.

The ICU Setting

Particular areas of the hospital are at increased risk for errors and near misses due to the nature of the area, type of patients, and medications and procedures used as part of patient care. The ICU is one such high-risk area. ICU patients usually have organ dysfunction or multiple organ dysfunction and are routinely exposed to high-alert medications (e.g., adrenergic agonists and antagonists, opioids, insulins, sedation agents, and anticoagulants). In one study involving two medical centers, the strongest predictor or risk factor for an adverse drug event or medication error in an ICU was the patient's illness severity [3]. Another study, involving medical and surgical ICUs compared to general medical and surgical wards, found that patients in an ICU were prescribed twice as many drugs as patients on general wards and had a twofold preventable and potential adverse drug event rate [4]. Another risk factor is the use of weight-based dosing for many medications, including anti-infectives, vasopressors, and anticoagulants. Weights may be estimated which can lead to under- or overdosing of necessary medications. Mathematical calculations are prone to error with weight-based dosing as well [5].

Epidemiology

In 1999, the Institute of Medicine reported, "To Err is Human: Building a Safer Healthcare System." This report estimated between 44,000 and 98,000 patients experienced a medical error and died per year. These errors have an estimated cost of \$37.6–50 billion due to the need for extra care, lost income, and disability [6].

Multiple studies have tried to provide further epidemiologic data regarding medication errors in

the ICU. The lack of standard definitions for medication errors and adverse drug events and underreporting of these types of medication safety concerns make it difficult to give an exact number to the incidence [7]. Most of these studies are observational. One study, involving a medical ICU and a coronary care unit (CCU) at an academic medical center, found 78% of serious medical events involved medications. These errors were mainly related to medication ordering or executing a particular treatment associated with a medication. The most common medication error was ordering the wrong dose, and the most common medications involved were cardiovascular drugs, anticoagulants, and anti-infectives. The overall medication error rate in the medical ICU was 12.7% and 12.1% in the CCU [8]. A similar observational study also evaluated medical and cardiac ICUs for medication errors. It found that 65% of medication events (1183/1805) had the potential for harm. Some events had more than one error, either the actual order had more than one error or the event led to errors in more than one step of the medication use process (see below for discussion of the "[Medication Use Process](#)"). Thirty-eight events (38/1805, 2%) were considered preventable. Seven of these preventable events led to significant patient harm (i.e., diarrhea, nausea, vomiting), 13 lead to serious patient harm (i.e., gastrointestinal bleeding, allergic reaction but not anaphylaxis, or altered mental status), and 18 were considered life-threatening (anaphylaxis, respiratory failure, etc.). Antibiotics were most commonly involved at 26% (10/38) of the events, while diabetic medications were next at 20% (8/38). Most medication errors occurred during the administration (39%) and prescribing/ordering (32%) stages [9]. In a pediatric ICU, an observational study showed that 151 prescribing errors occurred in 1129 orders, with 104 of these errors requiring intervention or resulting in patient harm. Wrong dosage was the most common error followed by wrong drug selection and missing information from the order. The most commonly prescribed medications, analgesics and anti-infectives, had the most frequent errors, with infrequently prescribed drugs (e.g.,

antihypertensives and antimycotics) demonstrating higher errors rates [10]. While it is difficult to compare different types of ICUs, one study did show that medical ICU patients experienced higher rates of medication errors than do patients in surgical ICUs [4].

Medication Use Process

The medication use process is a complicated series of sequential functions leading to a patient receiving medication. Each function of the process has multiple steps to ensure that it is completed correctly. These functions include prescription, transcription, dispensing, administration, and monitoring. Errors can occur at each function of the process. The most error prone functions are prescription and administration [11]. A recent study of prescribing errors in the ICU identified 360 errors in 286 prescriptions out of 534 total prescriptions. The most common prescribing error was omitted information with computer prescriber order entry. Examples of the omitted information included route of administration or diluent needed [12].

Several studies have focused on medication administration in the ICU aimed at determining the epidemiology of administration errors. In one observational study, pharmacists observed nurses in the preparation and administration of medications. Of 2009 medications administered, 132 (6.5%) involved errors. The most common errors were wrong dose (31%, 41/132), wrong rate (22%, 29/132), and wrong preparation technique (18%, 24/132). Almost 20% (26/132) of the errors were potentially life-threatening, and 42% (55/132) of the errors were potentially significant (e.g., underdosing, time errors, and physicochemical incompatibility) [13]. Another observational ICU study for medication administration involved only 3.3% of errors compared to the above but had a multidisciplinary team including pharmacists in place at time of observation [14]. This study supports the use of a multidisciplinary team to reduce medication errors. See “[Prevention Strategies](#)” below.

Prevention Strategies

Many prevention techniques, including technological advances, have been developed over the years to try to mitigate medication errors and adverse drug events. These prevention strategies focus on different functions in the medication use process or cross all areas of the medication use process. In general, a comprehensive program to target all parts of medication use and to obtain information in different ways allows for a broader scope of information and highlights different concerns. In one study, a program assessing voluntary reporting, chart review, and computer-based monitoring included monitoring for specific orders (naloxone) and alerts. All of these methods identified different medication safety concerns with little overlap in the problems identified [15]. Another study showed that direct observation revealed a higher incidence of potential and actual events when compared to chart reviews and solicited incident reporting [16]. In one ICU in Australia, a Medication Error Minimization Scheme (MEMS) has been implemented as part of an ongoing quality improvement project. The overall research design uses “Plan-Do-Study-Act cycles” to achieve small steps toward improving medication safety. With this MEMS, the ICU has seen an increased number of reported medication problems from incident reporting, staff surveys, focus groups, and chart review [17]. Once these concerns are known, strategies for prevention can be targeted and tested using methodology such as “Plan-Do-Study-Act cycles.”

Prescription writing, or ordering of a medication, is one of the areas more prone to error. Poor handwriting has led to mistakes with transcription in the past. With the introduction of computerized prescriber order entry (CPOE), it is no longer necessary to interpret a prescriber’s handwriting. In one study, the error rate of handwritten prescription orders contained 6.7% compared to 4.8% with CPOE. The handwritten prescription errors included omission of key information such as dosing, unit, or frequency. Types of errors for the CPOE orders included dosing errors, omission of writing order for a required drug, and

prescriber's signature [18]. In one ICU, the initiation of CPOE reduced prescribing errors from 27% to 3% when compared to a paper-based unit in the same hospital. Both CPOE and paper-based ordering had errors most commonly with cardiovascular and antibiotic medications [19]. In another study, CPOE implementation in a cardiac care unit showed a decrease in errors from 44.8% with handwritten prescription orders to 0.8% in computerized orders after full implementation of the CPOE system [20]. The evidence supporting the benefit of CPOE in reducing medication errors is grade II-3.

Decision support is considered an essential part of CPOE. This technology incorporates tools into the ordering system to aid providers in appropriate prescribing. It allows providers to automatically check for drug interactions, appropriate medications for elderly patients, and appropriate dosing for renal function among other functions. Some hospitals have even implemented decision support into antibiotic prescribing to ensure quality metrics are met and treatment guidelines are followed. In one recent study, five anesthesia-run ICUs were studied pre- and post-implementation of antibiotic decision support. Prior to implementation, only 61% of antibiotic orders adhered to guidelines. Immediately after implementation, 92% adhered to guidelines. This study also showed more antibiotic free days and a decrease in mortality when antibiotic guidelines were followed [21].

Once medications have been ordered, they must get dispensed and administered. Barcode medication administration has been implemented throughout hospitals as a way to ensure the "rights" of medication administration (i.e., right patient, right medication, right dose, right route, right time, right documentation, right reason, and right response). Using barcodes, one ICU study showed an improvement in correct administration times. This study used a direct observation technique to monitor medication administration errors. Prior to barcode medication administration, 18.8% of were administered at a wrong time. After implementation of barcode administration, the error rate was 7.5% [22]. The evidence supporting the benefit barcodes is grade II-3.

Another technological advance in drug administration has been the use of intelligent infusion pumps for intravenous medications. These infusion pumps have programmable libraries with point-of-care decision support for infusion rates and doses and will alert the nurse to problems related to medication administration. These pumps evaluate dose, dosing unit, rate, and concentration and prevent free-flow or "runaway" medication administration [23]. At the initiation of using this technology, a prospective study found numerous ways that these intelligent pumps could prevent error. The study also showed numerous ways in which providers were bypassing these techniques, such as not using the preprogrammed drug library with correct infusion rates [24]. In one Pediatric Intensive Care Unit, after adapting the drug library to its specific needs and acceptance by nursing staff, smart pumps were found to be very effective in reducing IV medication administration errors [25]. These intelligent pumps have the ability to intercept and log medication errors as well. One study in Germany showed that there were 717 instances of an alert firing for potentially harmful overdosing [26]. These pumps when used with barcode medication administration aid to ensure the "rights" of IV medication administration are met [23]. The evidence supporting the benefit of intelligent infusion pumps is grade II-3.

An additional way to prevent medication errors in the ICU is to have clinical pharmacists as part of the care management team. Clinical pharmacists have been shown to reduce errors, reduce costs, improve individualized care, and serve an educational function in the ICU [27]. A study involving a medical ICU and a coronary care unit at a large teaching hospital showed that preventable prescribing errors were reduced by 66% when a senior pharmacist was a full member of the patient care team [28]. Another study in China showed that pharmacists in the ICU intervened in errors related to medication dosing (152/407 interventions) (e.g., patient with renal insufficiency or on renal replacement therapy), drug omission (83/403 interventions), and potential for an adverse drug reactions (54/407 interventions) over a 6-month observational study [29]. In a

Dutch hospital, clinical pharmacists in the ICU reduced the incidence of prescribing errors from 190.5 per 1000 patient days to 62.5 per 1000 patient days and reduced the number of preventable adverse drug events from 4 to 1 per 1000 patient days [30]. Clinical pharmacists can also develop a training program for providers working in the ICU to teach clinically relevant errors related to preparation and administration of IV medications. A study of a Vietnamese program showed a reduction from 64% to 49% following implementation of such a program, and any residual dosing errors were less likely to be clinically relevant [31]. In addition to reducing errors, pharmacists in the ICU can aid in improving the management of infections, anticoagulation therapy, sedation, and analgesia for ICU patients [32]. The evidence supporting the benefit of ICU-based pharmacists grade II-3.

Drug–Drug Interactions

Drug–drug interactions (DDIs) are common and can lead to patient harm. The severity and drugs involved may differ in the ICU compared to other clinical settings [33]. Similar to medication errors, patients in intensive care units may be at risk for more severe drug–drug interactions due to the complexity of their illness, medications administered and their number, disease severity, and organ system dysfunction [5]. In one Dutch study, a computerized algorithm was developed to determine the frequency of DDIs. The DDIs were classified based on surveys from nine pharmacists and intensivists. After a consensus was reached, the group studied admissions to an ICU. A total of 16,122 DDIs were identified. Most commonly, antithrombotic and antibacterial agents were involved [34]. In another Dutch retrospective observational medical ICU study, 54% of all ICU patients experienced a potential DDI. The most common consequences for the DDIs were increased risk of an adverse drug reaction/side effect or toxicity. Management for the DDIs seen in the ICU often involved increased monitoring of some type (e.g., vital signs, laboratory studies, clinical monitoring for toxicity or effectiveness,

or for changes on the electrocardiogram) [35]. DDIs were associated with prolonged lengths of stay, 12 days versus 5 days for patients without DDIs, in the ICU [36]. Another prospective, case–control study showed that 6.65 DDIs occurred per patient. Pharmacodynamic and pharmacokinetic DDIs were common. Risk factors associated with risk of DDIs included female gender, age >50 years, use of >10 drugs, and ICU stay >7 days [37]. One recent study showed that 37% (187/501) of patients in a cardiac ICU have documented QTc \geq 500 ms. While no patients developed torsades de pointes, 63 patients (34%) had atrial dysrhythmias and 37 patients (20%) had ventricular dysrhythmias [38]. This acquired prolonged QTc syndrome may be a potential serious consequence of ICU stay since critically ill patients are at risk for QTc prolongation in addition to these patients receiving multiple medications and having organ system dysfunction which may lead to electrolyte abnormalities or changes in metabolic function due to reduced renal and hepatic function [39].

In the cardiothoracic ICU, anti-infectives, central nervous system, and cardiovascular agents were the main drugs associated with major DDIs or contraindicated because of another drug present in the patient's medication regimen. The predicted consequences of the identified DDIs included altered GI absorption of antibiotics, inhibition/induction of enzymes for drug metabolism, and QTc prolongation [40]. Another study in a cardiothoracic ICU revealed that 17.7% of DDIs were considered major (i.e., life-threatening and/or require medical intervention to minimize or prevent serious adverse events) or were contraindicated for concurrent use. The most common interactions were drug metabolism and drug synergy effects. Azole antifungals and fluoroquinolones were the most common drugs involved [41]. In another prospective, observational study of a medical ICU, 5–9% of potential DDIs were major or contraindicated for concurrent use. The most common consequences were changes to blood coagulation profiles, QTc prolongation, and inhibition of cytochrome P450 enzymes [33].

Summary of Recommendations

Use *Computer Prescriber Order Entry* with *Decision Support* to Decrease Prescribing Errors

Use Other Technologies, such as *Barcode Medication Administration* and *Intelligent Infusion Pumps* to Decrease Administration Errors

Seek the Aid of *Pharmacists* to Reduce All Errors, Reduce Costs, and Provide Education on Best Medication Practices in the ICU

Since the introduction of the imidazoline derivative clonidine, a topical nasal decongestant, in 1962, the number of agents in its class and the indications for their use have expanded greatly. Thousands of cases of clonidine exposure are reported to US poison centers annually (over 9700 exposures in 2014) with nearly 1 in 5 coded as resulting in moderate or major effect [1]. Exposures to guanfacine and other imidazolines increase the magnitude of the problem of alpha agonist exposures.

Xylazine, an analogue of clonidine, is used as a veterinary sedative, anesthetic, analgesic, muscle relaxant, and feline emetic agent (often in conjunction with ketamine) [2–4] and has been diverted as a drug of abuse [5] and adulterant of heroin [6, 7].

One might be tempted to discount the potential toxicity of medications in this class, but that would be shortsighted since interesting and useful agents continue to join this class, indications for some members of the class are expanding, and misadventures with these medications may have serious consequences. Dexmedetomidine is a recent addition to the class, approved by the US Food and Drug Administration in 1999. US Food and Drug Administration-labeled indications for dexmedetomidine were expanded to include procedural sedation in 2008.

The range of applications for these agents is ever broadening, and consequences of misuse may be severe. During its early use as a decongestant, the sedative and cardiovascular

This is an update of a chapter written with Kevin L. Wallace in the first edition of this text.

depressant effects of clonidine became apparent, sparking novel uses for this prototypical agent in the agonist/imidazoline group. Clonidine made its next debut in the treatment of hypertension and other applications followed. Clonidine and other imidazoline derivatives now have many indications, including the treatment of hypertension, mucous membrane congestion (naphazoline, oxymetazoline, tetrahydrozoline), sedation, anesthesia, pain control, migraine treatment, and muscle relaxation (tizanidine) [8], Tourette's syndrome [9], pediatric sleep disturbances [10], anxiety, attention-deficit hyperactivity disorder (ADHD) (guanfacine), treatment of menopausal hot flashes [11], glaucoma treatment (apraclonidine and brimonidine) [12], opioid detoxification [13], alcohol withdrawal [14], and smoking cessation [15]. In recent years, agents in this class have found application as adjuncts to anesthesia and to reduce anesthetic and analgesic requirements [16].

Biochemistry and Clinical Pharmacology

Clonidine and Related Agents

Clonidine is the most thoroughly studied of the centrally acting antihypertensive agents and is chemically and pharmacologically similar to other members of the imidazoline class, such as guanabenz and guanfacine. The development and clinical introduction of two newer oxazolines, moxonidine and rilmenidine, have led to better understanding of the mechanism of action of the imidazolines. These more recently developed agents are highly selective for the imidazoline receptor and have low affinity for α_2 -adrenergic receptors. They have improved side effect profiles compared with clonidine and are used primarily as antihypertensives. The initial introduction of clonidine as a mucous membrane decongestant was followed by the development and approval of several other imidazoline compounds for this indication, including naphazoline, oxymetazoline, tetrahydrozoline, and xylometazoline, which now are available over the counter or by prescription as decongestant solutions intended for nasal

or ocular use. As expected, based on their chemical and pharmacologic similarity, these agents have similar toxicity. Most reported cases of severe imidazoline intoxication pertain to clonidine.

Shortly after the initial introduction of clonidine, the compound's sympatholytic and hypotensive effects were noted [17], leading to its clinical application as an antihypertensive [18, 19] and subsequently to its use in the management of glaucoma [9, 15, 20–22], migraine headache [23], attention-deficit hyperactivity disorder [24], and, in conjunction with opioids or local anesthetics (or both) in epidural infusion, intractable cancer pain, postsurgical pain, and labor [25–28].

Knowledge of the existence of a central nonadrenergic binding sites responsible for the antihypertensive effect of clonidine was advanced in the 1980s after the investigation of structurally similar compounds synthesized to have fewer adverse effects [29]. Subsequently, the oxazoline compounds rilmenidine and moxonidine were approved for clinical application in several countries. These compounds have little α_2 -agonist potency compared with clonidine but nonetheless exert marked hypotensive effects. The study of these drugs has led to improved understanding of the imidazoline receptor concept, further described in the pathophysiology section. These compounds also possess antidysrhythmic activity [30]. Long-term use results in remodeling of the left ventricle. A hypoglycemic effect due to improved insulin sensitivity [31] without atherogenic effect also has been attributed to these agents [32–34]. The mechanism of action of clonidine and related agents is further summarized below in the discussion of the pathophysiology of toxic effects.

The activity of agents in this class is complex, and to understand them requires knowledge of both the centrally acting α_2 -agonist mechanism and the nature of imidazoline receptors. Three classes of imidazoline binding sites have been described and these are summarized in Table 1.

I₁-imidazoline binding sites meet important criteria associated with functional receptors: specificity in binding assays, linkage to physiologic functions, appropriate anatomic and cellular and subcellular localization, and binding affinities that

Table 1 Types of imidazoline receptors and their actions

Types of imidazoline receptors and their actions [161]	
I ₁ -receptor	Mediates sympathoinhibitory response to imidazolines to lower blood pressure
I ₂ -receptor	An allosteric binding site for monoamine oxidase, involved in pain modulation and neuroprotection
I ₃ -receptor	Regulates insulin secretion from pancreatic beta cells

correlate with functional drug responses. Additionally, I₁-imidazoline binding sites show physiologic regulation and endogenous ligands and are coupled to cellular signaling events. Activation of I₁ receptors causes choline phospholipid hydrolysis, leading to the generation of diacylglyceride, which in turn triggers the generation of second messengers including arachidonic acid and eicosanoids. Other cellular responses include inhibition of the Na⁺/H⁺ antiporter and the induction of catecholamine synthetic enzymes. Signaling pathways linked to the I₁-imidazoline receptor are reportedly similar to those of the interleukin family; therefore, I₁-receptors may be among the family of neurocytokine receptors [35].

Rilmenidine is an I₁-imidazoline receptor-selective antihypertensive agent. It acts both centrally and also in the kidney by inhibiting the Na⁺/H⁺ antiporter, providing antihypertensive action that has been compared with the efficacy of diuretics, beta-adrenergic blockers, calcium channel blockers, and angiotensin-converting enzyme inhibitors. While this agent is often used in addition to conventional agents, the tolerability and beneficial effects of this oxazoline (and moxonidine) warrant consideration of the oxazoline antihypertensives as first-line agents. Similar to moxonidine (discussed below) data support the role of this agent in the management of hypertension, suggesting important roles in special populations: patients with diabetes mellitus, dyslipidemia (due to beneficial effects on the metabolic syndrome), and chronic kidney disease (reduced microalbuminuria in patients with type 2 diabetes and hypertension). Rilmenidine has been reported to reduce left ventricular hypertrophy to a similar degree to other reference agents in patients at risk [36].

Moxonidine shares rilmenidine’s favorable effect in the face of insulin resistance.

Animal models suggest that moxonidine has a beneficial effect on insulin resistance and the metabolic syndrome resulting in improved glucose uptake and utilization and lowering lipid levels [37]. Metabolic and antihypertensive effects of moxonidine and moxonidine plus irbesartan in patients with type 2 diabetes mellitus and mild hypertension: a sequential, randomized, double-blind clinical trial [38]. Evidence also suggests that moxonidine may attenuate the sympathetic overactivity associated with the development and progression of chronic renal failure [39].

Dexmedetomidine and Etomidate

Dexmedetomidine is a selective adrenergic agonist that also possesses affinity for imidazoline receptors. Clinical studies have demonstrated that dexmedetomidine causes sedation and impairs memory [40]. This agent finds applications in critical care and operative care settings and should only be used where advanced airway and supportive care skills are available. Typical applications are for short-term perioperative and critical care sedation. Dexmedetomidine has been used as an adjuvant during anesthesia to augment sedation, anxiolysis, amnesia, and analgesia and reduce anesthetic and opioid requirements and particularly for its sympatholytic and cardiovascular stabilizing effects (similar to clonidine) in ventilated patients. Dexmedetomidine has been shown to blunt the sympathetic response to laryngoscopy, but impairs cognition and delays postanesthesia recovery [41]. The effect of dexmedetomidine on the adjuvant propofol requirement and intraoperative hemodynamics during remifentanyl-based anesthesia [42, 43]. Sedative, amnestic, and analgesic properties of small-dose dexmedetomidine infusions [44]. While some anesthetic agents may increase the QT interval, a decrease in the QTc intervals has been measured after the administration of dexmedetomidine to pediatric patients undergoing sevoflurane anesthesia [45]. Since

dexmedetomidine does not affect the synthesis, storage, or metabolism of neurotransmitters or block receptors, its hemodynamic effects may be reversible with vasoactive drugs [46].

Adverse effects reported with dexmedetomidine use include hypotension, hypertension, nausea, bradycardia, atrial fibrillation, and hypoxia [46–48]. First-degree or second-degree atrioventricular block has been observed in overdose. Adverse events associated with dexmedetomidine are usually observed during or briefly after loading of the drug [49].

Dexmedetomidine has found application in the management of alcohol withdrawal. Approaches to augmentation of therapy for patients with severe alcohol withdrawal after the failure of aggressive and symptom-guided benzodiazepine administration are not well standardized in the literature [50, 51]. In a small study of dexmedetomidine use as an adjunct to lorazepam and/or propofol, dexmedetomidine use was associated with less need for endotracheal intubation, quicker transfer to a lower level of care, and shorter hospital stays [52]. Other studies support the use of dexmedetomidine in severe alcohol withdrawal, citing reduced benzodiazepine requirements, low rates of mechanical ventilation, reduced alcohol withdrawal scores, and other benefits [53]. However, a single-site retrospective study comparing benzodiazepine use alone with dexmedetomidine *or* propofol therapy and adjusted for pneumonia or respiratory failure related to seizures prior to ICU admission suggests that adjunctive therapy with dexmedetomidine or propofol did not alter ICU course. The authors note that adjuncts to benzodiazepine therapy are usually selected in cases of severe withdrawal requiring high benzodiazepine doses and may reduce the amount of benzodiazepine required and facilitate the bedside titration of drugs to sedation goals, but did not have an appreciable effect on the course of patients with severe alcohol withdrawal syndrome [54].

Successful use of dexmedetomidine in the treatment of baclofen withdrawal after removal of an intrathecal baclofen pump from a 15-year-old patient with spastic quadriplegia and cerebral palsy has also been reported [55]. Expanded use

of dexmedetomidine on the generic market may facilitate broader application and future study of this agent.

Dexmedetomidine at a glance	
Indications, adults	Sedation of mechanically ventilated patients Procedural sedation of non-intubated patients Awake fiber-optic intubation
Administration	Continuous infusion with/without loading infusion
Precautions	Not recommended for use in those <18 years of age Reduce dosage in renal or hepatic impairment Heart block Ventricular dysfunction Increased risk of bradycardia and/or hypotension in patients with diabetes, chronic hypertension, hypovolemia, and the elderly Withdrawal symptoms in patients on infusion >24 h when discontinued abruptly Pregnancy category C
Drug interactions	Additive effects with vasodilators, negative chronotropic drugs, anesthetics, opioids, and sedatives. Consider dose reduction
Adverse effects	Hypotension, bradycardia, dry mouth, transient hypertension (upon loading), and sinus arrest

Many clinicians have experience with the imidazoline derivative etomidate, and some properties of dexmedetomidine may be better understood in that context. Etomidate, a predecessor of dexmedetomidine, is a widely used induction agent in emergency medicine and critical care, favored for its rapid onset, brief duration of action, cardiovascular stability (lack of hypotensive effect when compared with other imidazoline derivatives such as midazolam [56]), and lack of histamine release. Unfortunately, etomidate is also an inhibitor of 11-beta-hydroxylase, the enzyme responsible for the conversion of 11-deoxycortisol to cortisol [57–59]. Reports have long suggested that the use of etomidate may increase mortality in critically ill patients [60]. Meta-analyses of single-dose etomidate for rapid sequence induction in septic patients have further supported concern regarding adrenal

Fig. 1 Chemical structures of imidazoline, guanidine, and oxazoline compounds.

suppression and potentially associated higher mortality rates [61]. While there may be some methodological issues with this and similar studies to date and while observed effects of etomidate on mortality may be multifactorial [62] and independent of glucocorticoid replacement [63, 64], the use of alternative agents may be well advised and further randomized controlled study is suggested.

Given the similarity between etomidate and dexmedetomidine, concern has been raised regarding the latter's potential to cause adrenal suppression and increase mortality. A three-arm study (control with conventional induction and anesthesia, etomidate bolus, and dexmedetomidine loading + maintenance infusion) that enrolled 99 pediatric patients scheduled for congenital heart disease corrective surgery found that suppression of the adrenal cortex occurred in all three groups, function returned to baseline within 24 h of anesthesia induction, and the adrenal cortex function inhibition produced by etomidate is much more significant than that found in the control and dexmedetomidine groups [65].

Clinical Pharmacology

The chemical structures of clonidine and other imidazoline and oxazoline compounds are shown in Fig. 1. Clonidine is absorbed completely and rapidly from the gastrointestinal tract with onset of action in 30–60 min and essentially 100% bioavailability. Peak effects have been

reported to occur at 2–3 h with a duration of 8 h when administered in therapeutic amounts [17]. Topical imidazolines are well absorbed through ocular and nasal mucosa and the gastrointestinal tract. Although clonidine is excreted predominantly unchanged through the kidney, other imidazolines, guanidine, and oxazoline compounds vary in terms of their clearance mechanisms [66–69].

As might be inferred from the diverse use of clonidine mentioned earlier, the drug has been available in a variety of doses and formulations ranging from tablets to drops, solutions for injection, transdermal patches, and ophthalmic rods [70]. Systemic effects may result from the topical use of imidazolines. The use of clonidine 0.5% eye drops intended to treat open-angle glaucoma has been noted to lower substantially the systemic blood pressure [71].

Transdermal delivery of imidazolines is effective, but the conversion from oral to transdermal dosing is not predictable, presumably because of interpatient variability in transdermal absorption. Transdermal dosing of clonidine always should begin with a patch designed to deliver 0.1 mg/24 h applied once every 7 days to avoid accidental hypotension or intoxication [72]. The rate of drug absorption from patches also varies with the site of application on any given individual [73]. The use of transdermal delivery systems has resulted in unintentional drug transfer. Used transdermal patches of clonidine contain large residual amounts of medication. The high concentration of clonidine in the patches is required to assure

steady-state delivery of clonidine over the life of the patch. For example, a 0.3 mg/24 h clonidine patch contains 7.5 mg/10.5 cm [2] of clonidine before use and may deliver approximately 2.1 mg clonidine after the recommended 1 week of use, theoretically leaving about 5.4 mg clonidine in the discarded patch [74].

Discarded patches may pose a particular hazard to toddlers, who might retrieve these after they are discarded and then wear the patch or, worse, swallow them or suck or chew on them, liberating toxic amounts of clonidine [75]. Inadvertent parent-to-child transfer of a transdermal clonidine patch resulting in toxic effects in the toddler also has been reported [76]. In addition, we have witnessed hypotension resulting from excess drug delivery when multiple transdermal patches were worn by a confused elderly patient who mistakenly placed new patches of medication without removing the old transparent patches, which she had difficulty locating once they were placed on her skin.

Dexmedetomidine is metabolized by the liver via glucuronidation and cytochrome P450 prior to renal clearance of metabolites; therefore, this drug should be used with caution in those with hepatic impairment [77]. Of note, no significant gender or geriatric differences in pharmacokinetics have been observed with dexmedetomidine use, and pharmacokinetics are similar to those in normal patients for patient with renal impairment (Cr Cl <30 mL/min) [78].

Pharmacokinetics of Selected Imidazoline and Guanidine Drugs

Clonidine

Volume of distribution: 3.2–5.6 L/kg; 0.96 L/kg in children [20]

Protein binding: 20–40%

Active metabolites: None reported

Mechanisms of clearance: 40–60% excreted unchanged via the kidney

Elimination half-life: 12–16 h

Dexmedetomidine (linear intravenous pharmacokinetics)

Volume of distribution: V_{ss} (steady state) 118 L

Distribution half-life: 6 min

Protein binding: 94% (predominantly serum albumin) with negligible displacement by fentanyl, ketorolac, theophylline, digoxin, and lidocaine

Active metabolites: NA

Mechanism of clearance: Hepatic (glucuronidation and p450 CYP2A6); 95% of metabolites excreted in urine

Elimination half-life: 2 h

Guanabenz

Volume of distribution: 7.4–13.4 L/kg

Protein binding: 90%

Active metabolites: None reported

Mechanisms of clearance: Hepatic (<1% excreted unchanged via kidney)

Elimination half-life: 12–14 h

Guanfacine, immediate release

Volume of distribution: 6.3 L/kg

Protein binding: human plasma 64%; also binds moderately to erythrocytes

Active metabolites: NA

Note: No appreciable first pass effect

Mechanism of clearance: p450 (CYP3A4), glucuronidation, sulfation, and hepatic and renal clearance

Elimination half-life: 16–21.4 h

Oxymetazoline

Volume of distribution: NA

Protein binding: NA

Active metabolites: None reported

Mechanisms of clearance: 30–72% renal, 10–22% fecal, and 40–50% excreted unchanged

Elimination half-life: 5–8 h

NA, no information available

Data (pharmacokinetics table) from references 68–71, 79–83

Pathophysiology of Toxic Effects

While death due to unintentional pediatric exposure to these agents is relatively uncommon, overdoses are common and sequelae may be

substantial. Although adverse effects may be expected to increase in magnitude with escalating doses of imidazolines, toxicity does not always correlate well with dose, and even 1–2 doses of an agent such as clonidine may produce severe effects in a pediatric patient [82–84]. Severe intoxication with clonidine may produce transient hypertension followed by hypotension, coma, bradycardia, apnea, hypothermia, and miosis secondary to sympatholysis.

Initial speculation regarding the mechanism of action attributed the sedation, oral hyposecretion, and antihypertensive effects of clonidine to its activation of brainstem α_2 -adrenergic receptors [85]. Stimulation of these receptors results in inhibition of the nucleus tractus solitarius and ultimately in decreased norepinephrine release. This reduced sympathetic outflow from the thoracolumbar spinal tracts to the periphery has been thought to be the primary basis for the cardiovascular and neurobehavioral effects of these drugs [86, 87]. Sedation is thought to result primarily from the α_2 -agonist actions of imidazolines and guanidines, such as clonidine and guanabenz, in the locus coeruleus where this action may stimulate gamma-aminobutyric acid release [88]. The peripheral sympathomimetic effects of clonidine and other α_2 -agonists in this class (e.g., transient vasoconstriction and initial rise in blood pressure) have been explained on the basis of postsynaptic α_2 -agonist actions in vascular smooth muscle [89]. The presynaptic α_2 -receptor agonist actions of these drugs at central and peripheral adrenergic synapses, resulting in suppression of norepinephrine release, also may contribute to the antihypertensive effects of clonidine. Some evidence suggests that endogenous opioid-like substances may contribute to the sedation caused by clonidine [90]. If true, this may provide a physiologic basis for the anecdotally reported amelioration of mental status and apnea associated with clonidine overdose in children by naloxone.

The hypotensive effect of clonidine has been associated with dose-dependent release of nitric oxide and resultant vascular relaxation. Animal studies have demonstrated reversal of this effect through nitric oxide synthase inhibition [91]. The role of NO contributing to hypotension after

administration of clonidine suggests a potential antidotal role for methylene blue in severe imidazoline poisoning.

The development of more potent α_2 -agonists did not yield compounds with improved antihypertensive properties, leading to the hypothesis that the central antihypertensive action of these agents may result in part from agonist actions at specific imidazoline receptors. As previously noted, investigations of structure–activity relationships of compounds synthesized in an effort to reduce or eliminate the adverse effects (e.g., sedation) of clonidine led to development of the oxazoline class of antihypertensives (e.g., rilmenidine).

Parallels between effects resulting from the stimulation of opiate receptors and central α_2 -adrenergic receptors have led to speculation about a potential relationship between these receptors. This speculation is reinforced by the successful use of clonidine in detoxification regimens for opiate dependence [92, 93] and as a spinal analgesic [25–28]. Current hypotheses regarding such a link between opiate receptors and central α_2 -adrenergic receptors remain unproven.

In summary, clonidine and related drugs are central α_2 -adrenoceptor agonists that also bind to specific imidazoline receptors. These agents stimulate postsynaptic α_2 -adrenergic receptors in the vasomotor center of the medulla enhancing activity of inhibitory neurons and resulting in decreased sympathetic outflow with apparent increase in parasympathetic tone (resulting in decreased heart rate and blood pressure – postulated to be the result of endogenous opioid release). Some agents may also act peripherally on α_1 -receptors to cause a pressor response that is usually overshadowed by the central effects in therapeutic doses, but which may cause significant hypertension early in overdose. It is thought that some agents may also cause a peripheral presynaptic α_2 -agonist effect decreasing norepinephrine release and further potentiating the hypotensive effect of these agents. Finally, clonidine is also considered a partial α -receptor agonist due to its ability to inhibit the effects of other α -agonists [94].

Clinical Toxicology of Dexmedetomidine

As a selective and specific agonist of central α_2 -receptors, the binding of dexmedetomidine to receptors in the brain and spinal cord may be expected to inhibit neuronal firing resulting in hypotension, sedation, bradycardia, and analgesia. Of note, dexmedetomidine is severalfold more specific for the α_2 -adrenoreceptor than clonidine, a compound for which richer overdose data exists, and dexmedetomidine might be expected to behave differently. Furthermore, dexmedetomidine has an $\alpha_2:\alpha_1$ activity ratio of 1620:1 compared with 220:1 for clonidine [95].

Medication errors with dexmedetomidine have been reported. Misadventures may have resulted from clerical/transcription errors, unfamiliarity with the medication (mcg/kg/min administered as with many critical care medications instead of mcg/kg/h), and high patient acuity and high patient/staff ratios. Dexmedetomidine administration at higher than currently recommended doses per the package insert has been studied and appears to be well tolerated. Some work has demonstrated a biphasic response to dexmedetomidine administration with hypotension at low doses and hypertension at higher doses (though this has not been noted in the illustrative overdoses discussed below). The hypertensive effect of dexmedetomidine seen in a fraction of patients is perhaps due to dexmedetomidine activity at peripheral vascular α_{2b} -receptors as opposed to the activity at central α_{2a} -receptors where sedation and analgesia are believed to be mediated [48, 96–99].

Dexmedetomidine overdose in three perioperative patients has been reported to result in no hemodynamic instability but in oversedation which resolved within the hour. Magnitudes of the doses administered were as follows: one intraoperatively as an adjunct to anesthesia (192 mcg over 20 min) and two postoperatively (4 and 2 mcg/kg/h instead of 0.4 and 0.2 mcg/kg/h; 0.5 mcg/kg/min instead of 0.5 mcg/kg/h). No other sequelae were reported during the patients' hospitalizations.

While dexmedetomidine is reputed to have a substantial safety margin, an erroneous ninefold overdose of dexmedetomidine administered to a 3-year-old child (loading bolus of 100 mcg administered instead of 11 mcg as intended) tells a cautionary tale. The overdose resulted in miosis, bradypnea, bradycardia, hypotension, and deep sedation. The patient rapidly became unconscious; vital signs shortly after the overdose were heart rate 65/min, respiratory rate (RR) 8–10/min, blood pressure 70/40 mm of Hg, and oxygen saturation (SpO₂) 85%. The patient's respiratory depression was successfully managed with the administration of oxygen by mask with RR and SpO₂ improving to 14–16/min and 98%, respectively, over about 10 min. Endotracheal intubation was avoided. Boluses of normal saline and epinephrine infusion (tapered over 7 h) were used for cardiovascular support. The patient became responsive to painful stimuli in 3 h and was oriented after the passage of 7 h. Blood glucose was reported to remain normal [100].

An overdose in a 21-month-old female undergoing sedation for MRI resulted from pump misprogramming at a rate of 1 mcg/kg/min instead of 1 mcg/kg/h and resulted in administration of 196 mcg more dexmedetomidine over 20 than actually ordered. Upon discontinuation of the infusion, all vital signs were monitored and remained within normal age-adjusted parameters, the toddler returning to an Aldrete score of 9 (sufficient for discharge from the recovery room) within 20 min and an Aldrete score of 10 (baseline neurologic function) within 2 h [101].

The teratogenicity of dexmedetomidine is not well studied. The drug is known to cross the placenta. Similarly, long-term use of the drug is not well studied, but one might speculate that a withdrawal syndrome similar to that seen with clonidine might result from withdrawal after extended use. Adverse effects of dexmedetomidine may include hypotension, hypertension, nausea, bradycardia, atrial fibrillation, first- or second-degree atrioventricular block, and hypoxemia. Adverse effects are generally associated with loading doses or overdoses of dexmedetomidine, and dose reduction may minimize the adverse effects attributable to the use of this medication [46, 48].

Drug Interactions

The use of some imidazolines in conjunction with moderate or potent CYP1A2 inhibitors is contraindicated. For example, simultaneous use of tizanidine and fluvoxamine, a CYP1A2 inhibitor, resulted in a 33-fold increase in the tizanidine AUC (plasma drug concentration-time curve), potentially leading to exaggerated clinical effects [102]. Similarly, tizanidine should not be used in conjunction with fluoroquinolone antibiotics due to potential elevation of the serum tizanidine concentration [103].

The metabolism of clonidine is not well described, leaving some undocumented puzzles for the clinician regarding potential enzyme-mediated drug interactions. Current research suggests a major role for CYP2D6 in the metabolism and clearance of clonidine with relatively minor contributions by CYP1A2, CYP3A4, CYP1A1, and CYP3A5 [104]. Many hundreds of reported and potential drug interactions exist for clonidine. Among these are contraindications to the use of epidural clonidine in patients on blood thinners and cautions regarding amplification of the effects of sedative agents and agents with sedative side effects (increased sedation), beta-blockers and some calcium channel blockers (hypotension and bradycardia), digoxin (bradycardia), antidepressants (reduced antihypertensive effect), agents that promote orthostasis, and more [105]. Development of corneal lesions has been reported in rats treated with a combination of clonidine and amitriptyline within 5 days [106]. The combination of clonidine and high intravenous doses of haloperidol in patients with alcoholic delirium may lead to QT prolongation and arrhythmia [107].

Since a significant proportion of a guanfacine dose may be metabolized by CYP 3A4, inducers and inhibitors of this enzyme are best avoided during guanfacine therapy [79]. Although it has been suggested that dosage adjustments may be indicated when coadministering CYP3A4 inhibitors, it is likely safer to avoid concomitant administration of agents known to interact with guanfacine and other agents with similar metabolism. Interactions with cyclic antidepressants, azoles, MAOI, amphetamines, erythromycin,

and many other medications have been reported; clinicians are advised to check this extensive list.

Interestingly, a drug interaction between guanfacine and NSAIDs has been reported in a canine model. Indomethacin was reported to prolong the initial hypertensive response and to lessen the hypotensive effect of intravenously administered guanfacine. A less pronounced effect was noted with aspirin and ibuprofen [108]. Although the author is unaware of any trial of antidotal NSAID use in guanfacine or similar overdose, this finding suggests that such a future role may be plausible. On a cautionary note, administration of phenylbutazone decreases the pressor effect of guanfacine and enhances the hypotensive response in this same study. Accordingly, patients who use guanfacine and NSAIDs should be followed closely.

Clinical Presentation and Life-Threatening Complications

On the basis of numerous case reports and case series [109–116], the life-threatening effects of acute imidazoline intoxication may be characterized by initial hypertension and reflex bradycardia, followed by hypotension with bradycardia and a cyclical pattern of agitation alternating with coma/respiratory depression (bradypnea or apnea) that typically responds to vigorous physical stimulation. Syncope may result from the use or misuse of agents in this class. Peripheral vasoconstriction may manifest as skin pallor. Pupillary miosis is common (as a result of α_2 -receptor stimulation that decreases the prejunctional availability of norepinephrine leading in turn to reduced α_1 -sympathetic pupillary dilation and resulting in parasympathetically controlled miosis via muscarinic stimulation).

It is important to note that imidazoline ingestion may occasionally result in mydriasis [117] and that ocular administration of clonidine to patients with glaucoma may also result in mydriasis [118, 119]. Hypotonia, hyporeflexia, and hypothermia also may be present in severe intoxication. Bowel sounds may be reduced or absent, indicating gastrointestinal hypomotility.

Prominent α_2 -effects associated with imidazolines include sedation and reduced salivation. These common adverse effects of clonidine and guanabenz (compounds that possess strong α_2 -agonist properties) have limited their use at recommended doses by some patients. Although oral hyposalivation may be used to help characterize the toxidrome, this effect is less pronounced with oxazolines, such as moxonidine and rilmenidine, which have markedly reduced α_2 -agonist potency and higher selectivity for imidazoline receptors.

Abrupt cessation of clonidine has been associated with a hyperadrenergic syndrome characterized by what commonly is referred to as *rebound hypertension*. This effect may be dose dependent, may last up to a week, and has not been observed so far with the newer oxazoline group of antihypertensives [120, 121] although it may be prudent to taper these agents as is done with clonidine upon discontinuation. Clonidine doses are typically reduced over 2–4 days when discontinuing therapy in order to avoid rebound hypertension [106].

Diagnosis

A broad differential diagnosis should be considered in patients suspected of imidazoline, guanidine, or oxazoline drug toxicity, as for all patients presenting in coma (see ► Chap. 19, “Toxicant-Induced Alterations in Consciousness”).

The sympatholytic toxidrome may be characterized by an initial hypertensive phase followed by bradycardia, hypoventilation, sedation or coma, and miosis. Although uncommon, heart block may occur or SA nodal conduction may be affected. Hallucinations and seizures have been observed. The toxicologic differential diagnosis of central α_2 -agonist/imidazoline poisoning includes intoxication with opioids, β -blockers, calcium channel blockers, and digoxin (which may lead to increased automaticity/dysrhythmias unlikely with imidazolines). Like clonidine, each of these agents may be lethal, and each is potentially lethal to a toddler with a single dose. The differential diagnosis may extend to phenothiazines (e.g., chlorpromazine), true alpha blockers

(such as phentolamine, though this may often be distinguished by reflex tachycardia), acetylcholinesterase inhibitors (i.e., organophosphates or carbamates), barbiturates, and other sedative-hypnotic agents. Although routine toxicology immunoassay screens generally do not include imidazolines, these compounds can be identified in clinical specimens (e.g., urine) by gas chromatography/mass spectroscopy when clinically or forensically warranted. Where forensic concerns exist, it may be warranted to send specimens following chain-of-custody procedures.

Treatment

Compulsive supported care is the mainstay of alpha agonist toxicity. Because imidazoline compound-intoxicated or guanidine compound-intoxicated patients may develop light coma with or without apneic spells, special attention must be paid to airway and ventilatory status. Systemic oxygenation status and blood glucose concentration should be monitored early in the diagnostic evaluation. Given the potential for inhibition of glycogenolysis secondary to sympatholytic actions, the clinician should consider these patients to be at increased risk for hypoglycemia. Endotracheal intubation and mechanical ventilatory support are rarely required but may be warranted in severe intoxications. Successful management of imidazoline poisoning often has been limited to close observation with physical stimulation to terminate apneic episodes [111]. This may be especially true for unintentional pediatric exposures where the transient hypertension that follows ingestion does not require treatment.

Due to the potential for these agents to cause early central nervous system depression, many practitioners advise against the administration of activated charcoal. In the right setting, patients who present within 1 h of ingestion of clonidine or similar imidazoline tablets and those who have ingested clonidine transdermal patches might receive a single dose of activated charcoal (level of evidence III). However, this must be done cautiously and under close observation because

of the possibility of alterations in the patient's mental status and subsequent aspiration. Activated charcoal has not been shown to alter the outcome of patients poisoned by these agents. Whole-bowel irrigation may decrease gastrointestinal transit time of ingested transdermal patches and reduce absorption of the highly concentrated residual medication therein (level of evidence III) [75]. Completely expose all patients, examine for signs of trauma and injection sites, and remove any adherent clonidine patches.

Transient hypertension may be observed in patients who present early after overdose. This hypertension is generally of brief duration and often requires no therapy [122].

Severe hypertension following overdose can be treated (if necessary for signs of end-organ injury) only with short-acting, readily controlled vasodilator treatment (e.g., nitroprusside or nitroglycerin by intravenous infusion and titrated to effect) because it is likely to be transient and followed by hypotension as central sympatholytic effects become predominant.

Intravenous administration of crystalloid is the first-line therapy for hypotension in centrally acting antihypertensive overdose. The use of atropine for bradycardia in normotensive or hypertensive individuals may precipitate or prolong hypertensive crisis in individuals with a reflex increase in vagal tone secondary to peripheral vasoconstrictive effects. We recommend that atropine be avoided in imidazoline-poisoned patients except in the event of clinically significant bradycardia and hypotension (grade III recommendation). Intravenous norepinephrine, with or without atropine, is an appropriate choice of pressor in the treatment of hypotension associated with bradycardia [123].

Hypothermia can be managed with active or passive rewarming as indicated. Benzodiazepines are generally considered first-line therapy for imidazoline-induced seizures not caused by hypoxemia or hypoglycemia (grade III recommendation). Extracorporeal removal by hemodialysis has not been shown to be efficacious in enhancement of clonidine clearance [66], and neither is dialysis likely to be effective in cases of human overdose with xylazine due to its large volume of distribution [124].

There is no generally accepted specific antidotal therapy for imidazoline poisoning. Imidazoline-induced coma, respiratory depression, and miosis have suggested a role for intravenous naloxone as a means of reversing life-threatening clinical manifestations of toxicity, and there has been speculation regarding potential imidazoline-mediated release of an endogenous opioid-like substance without documentation. Reports of the efficacy of this treatment are inconsistent and are confounded by the typically cyclical course of the central nervous system effects of untreated poisoning [115, 116, 125–128]. It is possible that physical stimulation associated with the administration of this medication may be responsible for some reports of the efficacy of naloxone in reversing apnea and lightening sedation in some cases of imidazoline intoxication. Administration of naloxone to clonidine-poisoned children also has been reported to result in hypertension [129]. In cases in which naloxone has been suggested to have reversed clonidine-induced coma, the “response” has been transient and consistent with the untreated, cyclical course of the intoxication. The case of a 3-year-old child treated with naloxone after ingestion of 30 mL of 0.05% tetrahydrozoline solution reported by Holmes and Berman [130] illustrated this transient response. Two hours after the ingestion, incontinence of urine, hypotonia, and lethargy were noted. Naloxone (1.5 mg) was administered intravenously, followed by improvement in sensorium and increased heart rate and blood pressure. The effect was short-lived, however, and 10 min later the child again became somnolent with decreased pulse and blood pressure. The child subsequently was awake and alert approximately 8 h after ingestion without further administration of naloxone.

Despite the lack of convincing evidence that naloxone administration is beneficial in clonidine poisoning, its efficacy has not been excluded definitively by controlled clinical trials. If one is faced with the prospect of impending endotracheal intubation after the failure of vigorous stimulation to arouse an imidazoline-intoxicated patient in coma, it seems reasonable to proceed with an empirical trial of relatively high-dose naloxone (0.4–10 mg intravenously exercising

care to avoid precipitating withdrawal in opioid-dependent patients) as long as this intervention does not delay the institution of appropriate supportive care measures (level of evidence III). Perhaps the most appropriate empirical use of naloxone is in the setting of suspected or confirmed imidazoline intoxication to address the possibility of unrecognized or concomitant opioid toxicity.

Tolazoline, also an imidazoline compound, is a mixed central and peripheral α_2 -antagonist that has been used in the treatment of imidazoline intoxication, based on its theoretical potential for reversal of the central sympatholytic and peripheral sympathomimetic actions of imidazoline and guanidine drugs. Tolazoline use is not recommended, however, due to mixed clinical case experience and reported instances of hypertension, tachycardia, and arrhythmias after its administration [131]. Yohimbine, an indole derivative with central α_2 -antagonist actions, and idazoxan, an imidazoline and α_2 -adrenergic receptor antagonist, similarly lack sufficient supporting clinical evidence of efficacy and safety to recommend their use in the treatment of α_2 -agonist toxicity [132, 133].

Indications for ICU Admission in Clonidine and Other Imidazoline Derivative Poisoning

Coma/respiratory depression

Bradycardia/hypotension

Rebound hypertension from abrupt antihypertensive cessation

Ingestion of transdermal patch

Key Points in the Evaluation and Management of Clonidine and Other Imidazoline Derivative Poisoning

1. Severe toxicity, especially in young children, has resulted from the ingestion of small amounts (<15 mL) of over-the-counter topical and prescription imidazoline and guanidine preparations.
2. Clinical toxicity frequently presents as cyclical coma/respiratory depression alternating with agitation.

3. Appropriate treatment commonly is limited to routine supportive care and close observation, with physical stimulation as needed for episodes of apnea and intubation when required.
4. Although to date there is no convincing evidence that it reverses imidazoline-induced central nervous system depression, the empirical administration of high-dose intravenous naloxone in respiratory depression refractory to physical stimulation seems reasonable as long as it does not delay the provision of appropriately more aggressive supportive care (i.e., endotracheal intubation and mechanical ventilation).
5. Atropine use should be avoided in imidazoline-poisoned patients except in patients with clinically significant bradycardia and hypotension.
6. There is currently no antidote for centrally acting α_2 -agonist poisoning that has proved safe and effective, and the use of existing α_2 -adrenergic antagonists is not recommended.

Disposition

All symptomatic patients with clonidine or similar imidazoline exposures and all those who ingest clonidine transdermal patches should be admitted to a setting capable of close observation and critical care response. The onset of symptoms following the ingestion of transdermal clonidine patches may be delayed, and observation for a minimum of 24 h has been recommended since there are relatively few data regarding these ingestions and the amount of drug contained in a single patch is substantial (grade III recommendation) [134]. Whole-bowel irrigation with PEG-ELS may decrease GI transit time for ingested patches; however, insufficient data exist regarding benefits to clinical course and outcome. Those who present without symptoms shortly after ingestion must be observed in a setting capable of managing airway and hemodynamic

emergencies (emergency department, intensive care unit) due to the potential for decompensation within a few hours of overdose. In a study of 47 young children aged 9–84 months presenting with clonidine overdose, bradycardia occurred in 25, and apnea or depressed respiration was noted in 18. Thirty-four patients had symptoms within 1 h of presentation, but no patient was reported to have further clinical deterioration more than 4 h post-presentation [116].

An acetaminophen level should be obtained for all patients with suicidal ingestions, other coingestions should be considered, and psychiatric consultation is indicated. If a patient who has ingested a non-transdermal patch form of clonidine/imidazoline remains asymptomatic for 6 or more hours and is not suicidal, they may be discharged. Conservative practice suggests that those so discharged should be provided with return precautions and should have a reliable mechanism for return to the hospital in case of any unlikely delayed adverse effect.

Special Populations

Pregnant Patients

The teratogenicity of common prescription and over-the-counter imidazolines has not been studied completely. Given the relatively high fetoplacental penetration of imidazolines, developing fetuses are at potential risk of toxicity. Clonidine crosses the placenta readily with cord blood levels similar to maternal blood levels at delivery [135]. Maternal hypotension and hypoxia resulting from severe imidazoline intoxication also might result in reproductive toxicity. Fetal bradycardia is reported to occur with increased frequency in women who are administered epidural clonidine concomitantly with an

epidural anesthetic in labor [136, 137]. Infants born to women treated with oral clonidine late in pregnancy uncommonly may experience transient neonatal hypertension [138, 139]. Although high-dose animal studies of clonidine revealed effects on uterine blood flow, intra-amniotic pressure, and fetal oxygenation [140, 141], clonidine generally does not seem to be associated with significant adverse effects at doses that are nontoxic to the mother [142–144]. A case report of an infant with multiple severe birth defects (Roberts syndrome) born to a mother treated with 0.3 mg/day of clonidine throughout pregnancy for hypertension suggests, however, the preferable use of an alternative agent for the treatment of hypertension during pregnancy [145], with clonidine considered relatively contraindicated in this context. Clonidine crosses the placenta and is also secreted in breast milk [146].

Epidemiologic studies have not revealed definitive evidence of associations between the use of oxymetazoline and birth defects, despite one study in which maternal use of oxymetazoline, phenylpropanolamine, and pseudoephedrine revealed an association with gastroschisis. Pseudoephedrine and phenylpropanolamine apparently accounted for the major portion of this association [147–150]. A nonreactive nonstress test and late decelerations have been reported, however, in a patient presenting at 41 weeks' gestation. The fetus was delivered due to late decelerations and term pregnancy. The mother reportedly had overused an oxymetazoline-containing nasal spray before examination. Fetal heart rate changes were thought to result indirectly from decreased uterine perfusion or perhaps through a direct effect on the fetal central nervous system [151]. The safest policy is to advise against the use of imidazolines during pregnancy.

Pediatric Patients

Infants and young children are relatively susceptible to systemic effects from topical imidazoline use [152]. Pediatric patients also are at relatively high risk for poisoning due to their smaller body mass and greater likelihood of ingesting

imidazolines intended for topical use from containers supplied with dropper-type or spray-type dispensers resembling baby bottle nipples. Abundant case experience suggests that younger children are at particularly high risk for imidazoline-induced central nervous system depression and respiratory failure [109, 110, 113–116, 152, 153]. Clonidine has been found in human breast milk at concentrations about twice those in maternal blood, but the significance of this finding to nursing infants is unknown [135, 154].

Geriatric Patients

The elderly seem to be at increased risk of systemic adverse effects from topical imidazoline use. Bradycardia and hypotension have been reported in an elderly patient [155]. Some caution against the use of these drugs in the elderly seems appropriate.

Other Special Populations

Clonidine may be used to relieve symptoms in patients withdrawing from opioids, alcohol, or nicotine. Clonidine is used best in conjunction with other agents in the process of opioid or alcohol detoxification [156, 157]. Monotherapy with clonidine is not recommended, and clonidine alone does not reduce the incidence of seizures or delirium. Alcohol-dependent patients also should receive benzodiazepines [158]. Care must be exercised in treating opioid-dependent patients with possible polysubstance abuse because clonidine may mask symptoms of life-threatening sedative-hypnotic or ethanol withdrawal [159].

Exposures and Poison Prevention

Tetrahydrozoline, naphazoline, oxymetazoline, and xylometazoline currently are used in nasal and ocular decongestants. These are available in a wide variety of sprays and drops available by prescription and over the counter. Ingestion of 2.5 mL of 0.05% tetrahydrozoline (1.25 mg) has

resulted in respiratory depression. Drowsiness, sweating, marked hypotension, and shock resulting from the inadvertent ingestion of small amounts of these agents by children were recognized and reported by the mid-1960s [109, 153].

While the use of topical or systemic imidazolines in children younger than age 6 years has not been recommended in the Western English language literature for many years, such indications may persist in the literature of other regions. Aside from the age of the patient, some factors suggested as contributors to the intoxication of young children with “therapeutic” use of imidazoline decongestants include the difficulty of administering drops to children and packaging inadequate for proper dosing of children [110]. Recent child-resistant packaging of some imidazoline delivery devices promises to reduce unintentional exposure to these products.

Despite numerous reports of imidazoline intoxication after ingestion of 2.5 mL of solution, availability of over-the-counter imidazoline-containing nasal and ocular decongestants remains widespread.¹¹¹² Poison-prevention efforts should focus on increasing public and professional awareness of the hazard posed by imidazolines and on the selection of safe packaging, use, and storage of these agents.

Adult intoxication with clonidine may result from patient’s efforts to treat opioid or alcohol withdrawal with clonidine. Several reports of intentional ingestion of clonidine patches to ameliorate withdrawal symptoms may be found in the literature [134, 160]. Patients should be instructed in the safe use of imidazolines upon prescription, and compliance with safe handling of these medications should play a role in patient selection for imidazoline therapy.

Introduction

Beta receptor antagonists, or β -blockers, are used therapeutically for numerous conditions, including the long-term management of congestive heart failure, hypertension, migraine prophylaxis, and glaucoma. They can also be used for treatment of various movement disorders, social phobias, hyperthyroidism, and acute management of tachydysrhythmias. Toxicity from β -receptor antagonists is one of the most commonly encountered cardiac medications toxicologists encounter [1].

Clinically significant toxicity can occur when β -receptor antagonists can occur with therapeutic doses, drug-drug interactions, or overdoses. Toxicity at therapeutic doses typically occurs as a result of an adverse drug effect deriving from the normal physiologic properties of the drug, or from excessive systemic absorption after ocular instillation. One such example of the former would be the development of bronchospasm as a result of antagonism of pulmonary β -receptors in susceptible individuals. Drug interactions can cause serious toxicity with β -receptor antagonists, particularly bradycardia or heart block, resulting from the simultaneous use of a β -receptor antagonist with a cardioactive calcium channel blocker, such as verapamil or diltiazem. Some of the most serious manifestations of β -receptor antagonist toxicity occurs following intentional overdose or the administration of excessive doses.

Biochemistry and Clinical Pharmacology

Structurally, β -receptor antagonists are typically ethers of an aromatic group with a propylamine moiety bound to an isopropyl or similar group via the nitrogen terminus of the propylamine (Fig. 1). These agents share considerable structural similarity to the phenylethylamine β -receptor agonists. Beta receptor antagonists comprise a group of structurally related agents that act as antagonist at the β_1 -receptor, the β_2 -receptor, or both. In addition, these drugs are thought to exert varying degrees of antagonisms at β_3 - and β_4 -receptors, although the clinical relevance of this blockade is not entirely clear.

The β -receptor antagonists can be classified via several unique methods. Perhaps the most common method of classifying this class of drugs is based on their selectivity for the β_1 -receptor. Virtually all of the β -receptor antagonists used clinically are either selective for the β_1 -receptor or nonselective at both the β_1 - and β_2 -receptors (Table 1). It should be noted, however, that in overdose, selectivity is often lost and agents that are designed to provide antagonism exclusively at the β_1 -receptor may also inhibit the β_2 -receptor at supraphysiologic doses. Several of the β -receptor antagonists have unique pharmacologic properties, such as sodium channel blockade (also referred to as membrane stabilizing activity [MSA]), potassium efflux channel blockade, nitric oxide production, or intrinsic sympathomimetic activity (Table 1). Agents with intrinsic sympathomimetic activity have the potential for producing sympathomimetic effects during poisoning, which may limit the severity of the overdose. Lastly, β -receptor antagonists can be classified as being either lipophilic or hydrophilic. Those that are particularly lipophilic (e.g., propranolol) can readily cross the blood-brain barrier, thereby inducing central nervous system toxicity.

Pharmacokinetics

While there is variation among the different β -receptor antagonists, as a class most are

Fig. 1 Chemical structures of some common β -adrenergic antagonists. Note that the chemical side chain is widely conserved throughout this group

absorbed orally with a modest volume of distribution. However, some agents such as propranolol or carvedilol have an oral bioavailability of only 30%, whereas others, such as penbutolol or pindolol, have an oral bioavailability of nearly 100%. Certain β -receptor antagonists may be well absorbed following ocular application and result in high systemic concentrations [2–4]. Absorption after ocular administration is through the nasolacrimal duct and directly into the systemic circulation. Normal first-pass hepatic metabolism, a prominent feature of the oral administration of these agents, is thus bypassed.

Protein binding is quite variable, ranging from less than 10% for timolol to 98% for carvedilol. Most hepatically cleared β -receptor antagonists are metabolized by cytochrome P-450 2D6, an isoenzyme well known for its genetic polymorphism, as originally was shown for its role in debrisoquine oxidation [5, 6]. Although various 2D6 phenotypes have been described, they have not been shown to significantly influence the clinical course of β -receptor antagonist intoxication.

Timolol	No	Minimal	No	No	-1.99	

Pathophysiology

Beta Receptors

Beta adrenergic receptors comprise a group of interrelated receptors, which have a guanine nucleotide binding protein (G protein) – linked ligand binding sites. These transmembrane receptors have varying affinities for a variety of agonists and antagonists. There are four subtypes of β -receptors (β_{1-4}) [7].

The β_1 -receptor is found primarily in the heart, where it is the most abundant type of adrenergic receptor. It is widely distributed throughout the heart and, when stimulated, results in increased chronotropy, inotropy, automaticity, and action

potential conduction velocity. Most of the clinically significant effects from β -receptor antagonist intoxication occur as a result of blocking the cardiac β_1 -receptor. In addition to the heart, the β_1 -receptors are also found in the bowel, kidney, posterior pituitary, and adipocytes. In healthy individuals, nearly 80% of the β -receptors in the body are β_1 , while 20% are β_2 . The β_3 -receptors account for a very small number of total β -receptors [8].

Like the β_1 -receptor, the β_2 -receptor is also found in cardiac tissue, although in a considerably lower density than the β_1 -subtype. The β_2 -receptors are also found on arterioles and veins, where they cause vasodilation, and on smooth muscles of the airways, where they cause relaxation.

Fig. 2 Summary of where specific agents act in the cell. Isoforms of the β -adrenergic receptor and effects of their agonism. See text for further details. *cAMP* cyclic adenosine monophosphate, *PKA* protein kinase A

Most of the relevant toxicologic effects of the β_2 -receptor are due to the effects on the heart, arterioles, and airways. Beta₂ receptors are also found in the eye, uterus, skeletal muscle, pancreas, urinary bladder, spleen, liver, and intestines and throughout the gastrointestinal system.

The β_3 -receptor is best known for its action on adipocytes, in which the β_3 -receptors stimulate lipolysis. This receptor is also important in modulating the mast cell degranulatory response to immune system stimulation. The toxicologic significance of this receptor derives from its existence on the heart, however, where it may have a cardioinhibitory effect. The effects of the β_3 -receptor are most marked in patients with heart failure; however, as described subsequently, they may be important in the clinical manifestations of β -receptor antagonist intoxication and have a potentially significant influence on the response to therapy with adrenergic agents [7]. The β_4 -receptor is postulated to exist based on cardiostimulatory effects of β -receptor agonists that can be shown when the β_1 -, β_2 -, and β_3 -receptors are inhibited [7].

The physiology of β -receptors is complex [9, 10]. The β_1 -receptor (Fig. 2) exists in two forms – the active (R^*) and inactive (R) state, which exist in equilibrium. When a β -agonist binds to and stabilizes the R^* state, the equilibrium is shifted to an increased proportion of R^* . Agonist binding to R^* activates the stimulatory guanine nucleotide binding protein (G_s), which binds to and activates adenylyl cyclase, the enzyme responsible for the formation of cyclic adenosine monophosphate (cAMP), thereby activating protein kinase A. Protein kinase A subsequently induces phosphorylation of many proteins, including the voltage-gated L-type calcium channel. When these L-type calcium channels are phosphorylated, calcium influx occurs into the myocardium during phase II of the action potential. Phosphorylation of troponin I enhances muscle contraction by actinomycin. Phosphorylation of the ryanodine receptor and phospholamban on the sarcoplasmic reticulum enhances calcium release, which further stimulates excitation-contraction coupling. The β -receptor antagonists

bind to the R moiety, resulting in stabilization of the inactive form with a resultant shift in the equilibrium away from the activated receptor.

The β_2 -receptor also mediates several cardiac functions. While both the β_1 - and β_2 -receptors can be stimulated in a similar manner by β -antagonists, the β_2 -receptor can exist in a third isoform ($R^\#$) which acts primarily through an inhibitory protein, G_i [9]. Agents that bind to and stabilize $R^\#$ and mediate the β_2 -receptor-induced cardioinhibitory effects are known as inverse agonists. Most β -receptor antagonists function, to various degrees, as inverse agonists at this receptor, explaining the potential effects of these agents beyond that which would be expected from simple removal of the β_1 -receptor-mediated adrenergic tone.

The β_3 -adrenergic receptors constitute only a small fraction of the β -receptors on the heart and are cardioinhibitors, at least partially by a nitric oxide-mediated pathway, which seems to be independent of the pathways for the β_2 -receptor [10, 11]. The β_3 -receptor seems to be cardiostimulatory in the R^* state and may be cardioinhibitory in a G_i protein-linked manner via an $R^\#$ state analogous to that of the β_2 -receptor [7]. It appears that all β -receptor antagonists bind to the β_3 -receptor [7], although it is unclear which isoform of this receptor (R or $R^\#$) these agents stabilize.

When a β -receptor antagonist and a β -receptor agonist are pharmacologically present, there is a competition between them for binding to the various isoforms of β -receptors. The end result is a much greater dose of agonist required for a pharmacologic effect. The avid binding of the β -receptor antagonists to β -receptor means that the amount of agonist required to overcome the inhibition may be enormous.

Effects of β -Receptor Blockade

Airways

Agonism of the β_2 -receptor is associated with relaxation of smooth muscles of the airways and bronchodilation. In susceptible individuals, antagonism of the β_2 -receptor may result in significant

bronchoconstriction. It is not known to what degree, if any, inverse agonism at the β_2 -receptor causes bronchoconstriction.

Cardiac

There are many mechanisms by which β -receptor antagonists may exert negative inotropic and chronotropic effects on the heart, including β_1 -antagonism, inverse agonism at both the β_2 - and β_3 -receptors, membrane stabilization, and metabolic derangements. Agents with membrane stabilizing activity exert their effects via unique, non- β -receptor-mediated mechanisms. There also are certain uniquely individual properties of individual agents, the most prominent of which is associated with sotalol and described later.

Although normal human heart contains a large predominance of β_1 -receptors [12], there is a significant increase in the proportion of the β_2 -receptors in patients with heart failure [13]. It is, therefore, theoretically possible that the greater expression of inverse agonism that would occur with an increased proportion of β_2 -receptors may make the failing heart hypersusceptible to poisoning with these agents.

There is a theory that β -receptor antagonists, by virtue of their modulation of ion channels, cause hyperpolarization of the cell membrane and decreased inotropy and chronotropy [14].

Sotalol is a Vaughan Williams class III antiarrhythmic that increases the duration of the myocardial action potential and causes prolongation of the QT interval. Because QT interval prolongation is due to an increase in the duration of phase 2 of the action potential, as opposed to increased duration of repolarization, it is unclear whether sotalol predisposes to torsades de pointes; however, cases of this arrhythmia have been reported after intoxication with sotalol [15–17].

Membrane Stabilizing Activity

Agents with membrane stabilizing activity, such as propranolol, exert not only β -receptor antagonism but also sodium channel-blocking antiarrhythmic

effects characteristic of the Vaughan Williams class I agents. Clinically, this blockade manifests as QRS widening and may produce other myocardial effects similar to quinidine [18, 19]. Agents with membrane stabilizing activity may be characterized as class Ia antiarrhythmics in electrophysiologic action and toxicity (see ► Chap. 39, “Sodium Channel-Blocking Antidysrhythmics”). Treatment of the membrane stabilizing effects should include therapy targeting the sodium channel-blocking effects with sodium bicarbonate (see ► Chap. 39, “Sodium Channel-Blocking Antidysrhythmics”), in addition to therapy aimed at beta antagonists.

Blood Vessels

Stimulation of the β_2 -receptor causes vasodilation. It is anticipated that isolated β -receptor antagonist effects on vasculature allow for unopposed α -receptor-mediated vasoconstriction. However, the clinical manifestation is often difficult to appreciate due to the difficulty in separating the cardiac from the peripheral vascular effects.

Metabolic Effects

During routine physiologic conditions, the beta oxidation of fatty acids accounts for 60–80% of the myocardial energy substrate [20]. In therapeutic [21] or toxic [22] conditions, β -receptor antagonists cause a shift in the substrate preference of myocardium from free fatty acids to carbohydrates. Associated with this shift is a reduction in myocardial metabolic rate. This reduction may create an energy deficit from the heart. In an animal model involving therapeutic administration of a β -receptor antagonist, the administration of metoprolol resulted in inhibition of carnitine palmitoyltransferase I, suggesting reduction of fatty acid oxidation [20].

Clinical Presentation

Patients intoxicated with β -receptor antagonists present primarily with hypotension and cardiac bradydysrhythmias. In major intoxications,

a variety of additional effects may manifest. The clinical picture depends on the dose ingested, the underlying physiologic status of the patient, and the particular agent involved. Propranolol is one the most common agent implicated in severe or fatal ingestions [23].

Cardiac

The cardiovascular manifestations of β -antagonist poisoning typically are bradydysrhythmias, cardiac conduction defects, hypotension, and circulatory shock. Those agents with intrinsic sympathomimetic activity may cause hypertension. Severe β -antagonist poisoning may cause ventricular arrhythmias, including torsades de pointes and cardiac arrest. Sotalol is one such agent that has been associated with torsades de pointes in overdose [24]. Those beta blockers with sodium channel-blocking properties, such as propranolol, have been associated with intraventricular conduction delay [25].

Bradydysrhythmias

Because the heart has an intrinsic rhythm, the removal of β_2 -stimulation primarily prevents adrenergic stimulatory tone. This action by itself would not be expected to cause severe bradycardia in the absence of heightened vagal tone. However, inverse agonism, as described earlier, can theoretically worsen bradydysrhythmias. Those β -receptor antagonists with membrane stabilizing activity, particularly propranolol or oxprenolol, seem to be the primary cause of bradydysrhythmias [26], although they have been reported with other β -receptor antagonists as well [25, 27, 28].

Hemodynamically significant bradydysrhythmias may occur from the ocular administration of β -receptor antagonists, even at therapeutic dose [29–31]. Although bradydysrhythmias are less to occur in otherwise healthy patients, those with compromised cardiovascular function seem to be at greater risk of adverse events. These effects have been observed most frequently after the ocular administration of timolol [30–32], which is the agent often used to treat glaucoma. It has been described when timolol has been used

topically in the treatment of other conditions, such as hereditary telangiectasias [33]. Hypotension has also been described following ocular administration [4, 31].

Cardiac Conduction Defects

There have been many case reports of various dysrhythmias, including all forms of heart block, bundle branch blocks, junctional escape rhythms, and asystole associated with poisoning by many different β -receptor antagonists.

Pump Failure

Broadly speaking, pump failure following an overdose can be divided into three main categories: hypovolemic shock, distributive shock, and cardiogenic shock [34]. Cardiac pump failure from intoxication from β -receptor antagonists specifically may be due to hemodynamically significant arrhythmias, a decrease in inotropy, or both. This distinction is important, as the mechanisms have different therapeutic implications. Pump failure not attributable to bradydysrhythmias should be further characterized through measurement of hemodynamic parameters and echocardiography, unless it resolves with empirical treatment.

Hypotension

Hypotension has been associated with ingestions of nearly every β -receptor antagonists. The relative frequency of this effect has not been determined in a large case series, and it has not been associated with any particular β -receptor antagonists or pharmacologic characteristic. A study comparing the lipophilic, membrane stabilizing agent propranolol with atenolol, a β -receptor antagonists lacking these properties, showed no difference in the incidence of either systolic or diastolic hypotension after poisonings [25].

Pulmonary

Many pulmonary complications may be anticipated with poisoning from β -receptor antagonists. Patients with a depressed level of consciousness may develop hypoventilatory respiratory failure and should be considered at increased risk for

aspiration. The blockade of the pulmonary β_2 -receptors can result in increased airflow resistance, manifesting clinically as bronchospasm. Patients with severe cardiovascular dysfunction may develop adult respiratory distress syndrome.

Respiratory Depression

There have been multiple reports of respiratory depression after overdose with β -receptor antagonists. Respiratory failure seems to be secondary to cardiovascular or central nervous system depression and would not be expected independent of these effects. A clinical study comparing the propensity to cause bradypnea between atenolol and propranolol did not show any difference [25].

Neurologic

The two primary neurologic manifestations of β -receptor antagonist intoxication are central nervous system depression and seizures. The former may be secondary to cardiovascular depression and decreased cerebral perfusion. Lipophilic agents, such as propranolol, may have a more direct effect on the central nervous system.

Seizures have been reported with a variety of β -receptor antagonists in overdose. Propranolol, however, is disproportionately affected. Most of these patients have hemodynamic instability and intraventricular conduction delay [25]. In one series, two-thirds of patients ingesting more than 2 g of propranolol experienced a seizure [25]. Seizures are not clearly associated with a Glasgow Coma Scale score less than 15 or QT prolongation [25].

Miscellaneous

Intoxication with β -receptor antagonist can be expected to produce other effects that can complicate therapy, including hypoglycemia, rhabdomyolysis, metabolic acidosis, and acute kidney injury, the latter of which is most likely due to hypoperfusion.

Diagnosis

The diagnosis of β -receptor antagonist poisoning is a clinical diagnosis that should be suspected on the basis of the history and physical exam

findings. Relative or absolute hypoglycemia may be an important diagnostic clue. Most drugs of abuse screens will not be abnormal on the basis of β -receptor antagonist toxicity. Comprehensive drug testing, however, can confirm the exposure. Quantitative serum drug concentrations, while helpful in confirming the toxicity, are usually not routinely available and can be useful only for retrospective verification of the diagnosis. Confirmatory testing is not required to make the diagnosis of β -receptor antagonist toxicity.

Treatment

As with all poisonings, the treatment of β -receptor antagonist often relies on appropriate and aggressive supportive care, including airway support for standard indications, and monitoring for potential complications.

Decontamination

The administration of activated charcoal may reduce blood concentrations of ingested β -receptor antagonist. In a volunteer study of eight healthy subjects who ingested nadolol and then consumed 3 g of charcoal over 9 h, the area under the curve decreased after charcoal administration [35]. However, there are no studies demonstrating beneficial effect of activated charcoal following β -receptor antagonist overdose. If a patient presents following an ingestion of a β -receptor antagonist and presents within 1 h, it is reasonable to consider a single dose of activated charcoal. However, the clinical utility of this intervention is debatable because the effect on outcome is unknown and there is a risk aspiration from a declining mental status that may occur during activated charcoal administration.

Whole bowel irrigation with electrolyte-balanced polyethylene glycol solutions has been touted as an alternative to activated charcoal. There are no data supporting the use of this technique in the treatment of β -receptor antagonist toxicity, and its use is not recommended. The most recent position paper from the American

Table 2 Pharmacokinetics of β -receptor antagonists that are amenable to extracorporeal removal

Atenolol	1.1	6–16%
Sotalol	1.2–2.4	0

Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) concludes there is insufficient evidence to routinely recommend whole bowel irrigation, but acknowledging its use can be considered in potentially toxic ingestions of sustained release preparations [36].

Patients who have β -receptor antagonist toxicity secondary to ocular administration may benefit from eye irrigation, although there are no randomized trials demonstrating benefit of ocular irrigation.

Most of these agents have a high volume of distribution. Consequently, it is unlikely that enhanced elimination techniques are likely to be beneficial in the treatment of most acute β -receptor antagonists. However, acebutolol, atenolol, and sotalol may be amenable to extracorporeal removal (Table 2).

Cardiovascular Effects

Bradydysrhythmias

The various treatment modalities available for β -receptor antagonist-induced bradydysrhythmias have not been studied in individual or comparative trials. There is published case experience with the use of atropine, glucagon, β -receptor agonists, phosphodiesterase inhibitors, insulin, lipids, electrical pacing, intra-aortic balloon counterpulsation, and extracorporeal circulatory support for this indication.

Atropine, a muscarinic anticholinergic agent, increases the heart rate through its vagal-lytic effects. Although atropine may provide a transient increase in the cardiac rate, its effect is variable and short lived. Repeated doses may produce both central and peripheral anticholinergic toxicities.

Fig. 3 Sites of action of pharmacologic therapies that may be used in the management of β -receptor antagonists

Its primary use is limited to the initial stabilization of a bradycardic, hemodynamically unstable patient.

Glucagon has been widely suggested as an antidote for β -receptor antagonist poisoning. There have been multiple case reports, although generally these were in uncontrolled clinical cases involving several pharmacologic therapies. Several recent meta-analyses have found inadequate evidence to support its use [37, 38]. Nonetheless, many review articles continue to recommend its use as a possible treatment modality for the treatment of β -receptor antagonist toxicity [39–43]. The reported action of glucagon stems from its ability to stimulate adenylate cyclase independently of the β -receptor (Fig. 3). When used for the treatment of poisoning, glucagon is typically administered as a 5–10 mg intravenous bolus for adults, followed by a continuous infusion. The pediatric bolus dose is 50–150 mg/kg. Some preparations of glucagon have been packaged with a phenol-containing diluent. Because the doses of glucagon are higher than doses for other purposes, patients may receive an excess amount of phenol if the diluent is used. If the diluent is phenol, it should be replaced with normal saline or dextrose in water to reduce the risk of phenol toxicity. One of the major adverse effects with glucagon is vomiting. Prior to administration of glucagon, patients should receive a liberal dose of

antiemetics, as retching and vomiting can increase vagal tone, theoretically worsening bradycardia.

The use of β -receptor agonists, aimed at overcoming receptor blockade competitively, may be attempted in cases of hemodynamically significant cardiac bradydysrhythmias. The available options include isoproterenol, dobutamine, norepinephrine, epinephrine, and prenalterol. There are few data to rely on for assessing the effects of β -agonists in the treatment of these bradycardias. For patients who are refractory to simple supportive therapy, an empirical trial with a dobutamine or isoproterenol infusion can be attempted. As described subsequently, isoproterenol or dobutamine may worsen hypotension or cause cardiac dysrhythmias and should be used cautiously and only in a well-monitored patient. The typical adult dose of isoproterenol for conditions not related to β -blocker poisoning is 2–10 μ g/min. Because of the potential adverse effects of this therapy, the lowest effective dose should be used. The typical pediatric dose is 0.1–1.5 μ g/kg/min, with the lowest effective dose suggested. As described subsequently, however, it is unlikely that conventional doses of isoproterenol or dobutamine (typical doses of 0–20 mcg/kg/min) would be effective in a patient with serious β -blocker poisoning.

There are few published data on the use of dobutamine or epinephrine as a β -adrenergic agonist in patients poisoned by these agents. Because

of the high binding affinity of β -antagonists to the β -receptor, it is likely that high doses of receptor agonists would be required to overcome the blockade competitively. This likelihood may explain some cases where adrenergic agents fail. It has been calculated that a 10,000 times increase over standard isoproterenol dosing would be required to overcome the blockade induced by an overdose of propranolol [26]. For β -adrenergic agents that have any α -agonist properties, the administration of high doses may increase afterload to the point of causing adverse effects on cardiac hemodynamics or coronary perfusion or both, in part due to the unopposed α -adrenergic agonism that occurs as a consequence of β -receptor antagonist intoxication.

Cardiac pacing may be attempted for the treatment of bradyarrhythmias, although there is little clinical experience with this in the management of β -receptor antagonist intoxication. Successful use of the intra-aortic balloon pump has been reported in isolated β -receptor antagonist intoxication [44]. Similarly, in patients unresponsive to all other measures, extracorporeal cardiac support could be attempted [45, 46].

Phosphodiesterase inhibitors such as inamrinone or milrinone theoretically should have a positive chronotropic effect on the myocardium because the β -receptor exerts its effect by increasing intracellular cAMP, a molecule-metabolized phosphodiesterase. Phosphodiesterase is bound to the sarcoplasm in the heart. By inhibiting this enzyme, there is enhanced release of calcium from the sarcoplasm [10]. There is animal data demonstrating increased cardiac index with these agents [47, 48]. However, in other canine models of propranolol toxicity, the combination of glucagon with a phosphodiesterase inhibitor proved inferior to glucagon alone [47, 49, 50].

If inamrinone is utilized, the typical loading dose is 0.75 mg/kg as a bolus given over 2–3 min, followed by an infusion of 5–40 mcg/kg/min. Milrinone typically is administered as a loading dose of 50 mcg/kg over 10 min, followed by an infusion of 0.375–1 mcg/kg/min. These dosing protocols should be adjusted in patients with significant renal insufficiency.

Intravenous lipid emulsion therapy has emerged as a novel therapy for treatment of lipophilic drug toxicities. While various theories exist, one such theory, the so-called “lipid sink” theory, suggests that the administration of a high concentration of fat into the vasculature results in a redistribution of a lipophilic drug out of the periphery and into the vascular compartment [51]. However, it should be noted that this theory may not fully account for the clinical effects [52].

There are no randomized trials of intravenous lipid emulsion therapy in the treatment of β -receptor antagonist toxicity. Animal studies have examined intravenous lipid emulsion therapy for the treatment of propranolol, atenolol, and metoprolol toxicities. This data demonstrate equivocal efficacy with in some studies showing some benefit [53, 54] and others failing to confirm any benefit to its use [55, 56]. Numerous human case reports have described its use for the treatment β -antagonist toxicity [57–62]. While numerous dosing recommendations have been suggested, one involves the administration of 1.5 mL/kg as an intravenous bolus, followed by 0.25 mL/kg/min for 30 min [63].

Cardiac Conduction Defects

As described earlier, various degrees of cardiac conduction defects have been observed after intoxication with β -receptor antagonists, including agents with and without membrane stabilizing activity. There has been no systematic study of this phenomenon, and few data are available in the published literature on its treatment. Nonetheless, it is recommended that any intraventricular conduction delay be treated with intravenous boluses of sodium bicarbonate (e.g., 1–2 mEq/kg with additional therapy based on response). Minor degrees of heart block in an otherwise hemodynamically stable patient can be managed expectantly. If the heart block is associated with significant bradycardia, it is possible that it may resolve with treatment of the latter, as described earlier. The fluid and electrolyte status of the patient also should be optimized. If the heart block is significant enough to cause pump failure, treatment should be initiated as described in the following section.

Pump Failure

There have been no randomized clinical trials to date addressing the optimal therapy of β -antagonist-induced reduction in myocardial contractility. Pump failure due to hemodynamically significant bradycardias should be treated initially as described earlier. Pump failure that is not solely rate related can be managed, however, by the administration of inotropes, glucagon, or possibly insulin or phosphodiesterase inhibitors.

Pump failure resistant to pharmacologic interventions and optimal management of fluid status may require the use of a left ventricular assist device or extracorporeal circulation. If pump failure is refractory to initial therapeutic approaches, it may be helpful to obtain precise hemodynamic parameters through invasive monitoring (grade III). The clinical benefits and risks of this intervention have not been studied, however.

Some inotropic agents (e.g., dobutamine) act by stimulating cardiac β_1 -receptors and are expected to be antagonized competitively by the β -blocker. These agents may not be clinically effective, although a cautious empirical trial of this approach cannot be criticized. Theoretically, much higher doses of β -agonists may be necessary than doses typically used in the absence of β -receptor antagonist poisoning. Of the various options for β_1 -specific inotropes, dobutamine is the most appropriate based on theoretical considerations (evidence grade III). These effects may be magnified at higher doses. An emerging concern regarding the use of β -antagonists in the presence of a β -receptor antagonist relates to the cardioinhibitory β_3 -receptor. It is possible that blockade of the cardiac β_1 -receptor and β_2 -receptor could cause adrenergic inotropes preferentially to agonize the β_3 -receptor. In the presence of nadolol, isoproterenol exerts an inhibitory effect on dP/dt in the human myocardium [7].

The use of glucagon in the management of β -receptor antagonist toxicity was described earlier. Several animal studies have demonstrated beneficial effects following the use of glucagon in the treatment of β -antagonist toxicity (evidence grade IIb) [39–43]. One porcine study compared

vasopressin at 0.0028 units/kg/min titrated up to 0.014 units/kg/min with glucagon (0.05 mg/kg bolus followed by an infusion at 0.15 mg/kg/h). There was no difference in survival or hemodynamic parameters between the groups [64].

High-dose insulin has been postulated to improve hemodynamics via multiple different mechanisms, including increased inotrope, improved carbohydrate uptake by cardiac myocytes, and inhibition of free fatty acid [65]. However, it should be noted that supraphysiologic doses can produce vasodilation [66]. Based on several dog studies, hyperinsulinemic euglycemia therapy has been suggested as a possible treatment [40, 66]. Several non-randomized case reports and case series have been published, with the majority reporting benefit [67–70]. When used in this setting, however, hypokalemia and hypoglycemia are common. Many patients required prolonged concentrated dextrose infusions after insulin was discontinued [67]. While dose recommendations vary, one recommended dose involves an intravenous bolus of 1 unit/kg of regular insulin, followed by a continuous infusion of 1–10 units/kg/h (evidence grade IIc–III) [68]. There are no randomized trials in humans comparing insulin therapy with vasopressors for the treatment of β -receptor antagonist toxicity. The clinical pharmacology of high-dose insulin therapy is discussed in more detail in the chapter devoted to that antidotal treatment in the antidote section.

Vasopressors may be beneficial in the treatment of vasodilation secondary to β -receptor antagonist stimulation of the β_2 -receptors (grade IIc–III). Dopamine, norepinephrine, and epinephrine are commonly used. None of these agents have been systematically studied in this setting, however. An appropriate approach to using vasopressors in these patients is to start them at standard doses and quickly titrate the dose upward, while monitoring their efficacy in the particular patient by assessment of hemodynamic response. It should be noted that when treating toxicity from combined α - and β -blocker (e.g., labetalol, carvedilol, and celiprolol), the use of dopamine may theoretically exacerbate hypotension (grade III).

Noncardiovascular Effects

Respiratory depression, bronchoconstriction, central nervous system depression, seizures, hypoglycemia, and secondary complications such as acute kidney injury and rhabdomyolysis should be treated by standard measures for the approach to these complications in the intensive care unit. It should be anticipated, however, based on theoretical considerations, that attempts to treat bronchospasm with β -agonists may be unsuccessful due to the blockade of β -receptors. Similarly, because this bronchospasm is due to loss of β -adrenergic tone and not inflammation, it is unlikely that corticosteroids would offer significant therapeutic effects. Alternative bronchodilator approaches with greater potential efficacy include anticholinergic agents (e.g., ipratropium, glycopyrrolate), phosphodiesterase inhibitors (e.g., aminophylline), and possibly glucagon. Seizure secondary to β -receptor antagonist poisoning, seen most commonly with propranolol, should be treated in the same manner as other toxicant-induced convulsions (grade III) (see ► [Chap. 20, “Toxicant-Induced Seizures”](#)).

Special Population

Pediatric Patients

There is little information concerning significant differences in the pathophysiology, presentation, or treatment of β -receptor antagonist intoxication in children compared with adults. Among more than 10,000 β -receptor antagonist intoxications reported to US poison centers, more than 3,000 involved children age 12 or under [23]. A 7-year retrospective study of cases reported to a regional poison center in the United States evaluated children younger than 7 years old with β -receptor antagonist ingestions. As is typical for ingestions in children of this age, most involved either a small number of pills or only the suspicion of ingestion [69]. Only 8 of the 378 children evaluated developed any significant signs of toxicity. The toxicities that did occur

were bradycardias, lethargy, and hypotension. These were manifest at a median of 3 h post ingestion, with a maximal time from ingestion of 3.5 h. This study did not have enough cases with sustained release preparations to reach any conclusions regarding ingestion of these formulations. A different poison control center-based study examined 208 pediatric patients aged 6 months to 6 years with unintentional β -receptor antagonist. In that study, the majority of patients consumed one or two β -receptor antagonists. No cases of serious toxicity due to the β -receptor antagonist were developed, but one child did have a charcoal aspiration following gastrointestinal decontamination [71]. From the limited information available, it seems that the clinical presentation of β -receptor antagonist intoxication in children is similar to that in adults, and with the exception of sustained release preparations, children who will become symptomatic tend to do so within several hours. Patients who are asymptomatic but who have ingested sustained release preparations should be observed for a longer time. Asymptomatic pediatric patients who present following a β -receptor antagonist ingestion should be observed for 6 h for immediate release preparations and 8 h for sustained release preparations [72]. Asymptomatic patients who ingest sotalol should be observed for 12 h. Symptomatic patients should be admitted.

Elderly Patients

Patients with impaired cardiopulmonary reserve are more likely to develop clinical effects following an ingestion compared with those patients with normal physiologic reserve. In one study of patients with unintentional, supratherapeutic ingestion of their own β -receptor antagonist or calcium channel antagonists, 10% of patients developed signs of toxicity and 7% required hospital admission [73]. The management of patients should not differ based on age, although elderly patients may be more predisposed to develop severe effects.

Pregnant Patients

Most of the adverse experiences associated with β -receptor antagonist in pregnancy involve propranolol, which seems to cross the placenta and may concentrate in the fetus [74]. Bradydysrhythmias, hypoglycemia, respiratory depression (and even neonatal apnea), and circulatory collapse have been described in women who received propranolol before delivery [74–76].

A case of neonatal respiratory depression, hypotonia, and circulatory collapse was reported in a 33-week-gestation neonate delivered by cesarean section whose mother received intravenous labetalol before surgery [75]. A case report of a major overdose of metoprolol in a woman in her 20th week of pregnancy described cardiac arrest in the mother. Despite successful resuscitation, the event led to fetal demise [73].

Breast-Feeding Patients

Most β -receptor antagonists that have been studied in regard to breast-feeding are excreted in breast milk. A case report described an infant with β -receptor antagonist intoxication from breast-feeding by a mother who was treated with atenolol [77].

Indication for ICU Admission in β -Receptor Antagonist Poisoning

Hemodynamic instability
Coma or seizures
Bronchoconstriction not responsive to initial bronchodilator therapy
Dysrhythmias

Common Errors in β -Blocker Poisoning

Not realizing that therapeutic use of β -receptor antagonist-containing eye drops can cause significant toxicity
Failing to provide aggressive supportive care
Failure to continue titrating infusions due to reaching a predefined “maximal” dose

Key Points in β -Blocker Poisoning

β -Blockers may cause the following:

Bradydysrhythmia
Intraventricular conduction delay
Atrioventricular blocks
Hypotension
Central nervous system depression and seizures
Bronchoconstriction
Secondary complications deriving from the above, including renal failure

Therapeutic options beyond supportive care comprise

Gastrointestinal decontamination
Atropine
Phosphodiesterase inhibitors
Glucagon
Insulin
Lipid resuscitation therapy
Cardiac pacing
Left ventricular assist
Extracorporeal membrane oxygenation
Extracorporeal drug removal for certain agent

The role of calcium in physiologic processes has long been recognized. In about 1960, it was first noted that calcium channel antagonists, which were being developed as vasodilators, had negative inotropic and chronotropic effects [1]. This observation gave rise to the concept that reducing calcium influx into myocardial cells and arterial vascular smooth muscle could negatively modulate excitation–contraction coupling, accounting for their vasodilating and negative inotropic effects [2]. Subsequently, it was recognized that inhibiting the inward calcium flux decreased the rate of spontaneous depolarization of cardiac pacemaker cells. Because this inward calcium current is slow compared with the fast sodium channel of cardiac myocytes, the former has been called the *slow calcium channel*, frequently referred to as simply the *calcium channel* [3].

The vasodilating and negative chronotropic effects of calcium channel antagonists have led to their development for many important indications, such as the treatment of hypertension, cardiac tachyarrhythmias, arterial vasospasm, angina pectoris, hypertrophic cardiomyopathy, congestive heart failure, premature labor, and pulmonary hypertension [4].

Several classes of calcium channel antagonists are in use. These classes vary in their effects on arterial smooth muscle and the heart. The pharmacologic actions of the various agents on these two organs account for their major clinical effects, as well as their toxicity, when used therapeutically [2].

The major calcium channel antagonists in clinical use around the world are verapamil, nifedipine, diltiazem, and amlodipine. As described in this chapter, the first three of these drugs are prototypes of the three major distinct classes of calcium channel antagonists; most of the data concerning the toxicity of these respective classes come from observations on these three specific agents. To the extent that information is available on the toxic effects of the other calcium channel antagonists, these are described as well [2].

Biochemistry and Clinical Pharmacology

Five classes of calcium channel antagonists are in clinical use (Table 1), although verapamil, diltiazem, and members of the dihydropyridine class have been the most frequently employed.

Table 1 Calcium channel antagonists

Class	Agent(s)	Class effects		
		Heart rate	Peripheral arterial tone	Cardiac contractility
Phenylalkylamine	Verapamil	↓	↓	↓↓
Dihydropyridine	Amlodipine	↑	↓↓↓	±
	Felodipine			
	Isradipine			
	Nicardipine			
	Nifedipine			
	Nimodipine			
	Nitrendipine			
	Nisoldipine			
Benzothiazepine	Diltiazem	–/↓	↓↓	↓↓
Diphenylpiperazine or tetralene	Mibefradil ^a	↓	↓↓	–/↓
Diarylaminopropylamine or diarylaminopropylether	Bepridil	↓	↓	↓

^aWithdrawn from the market in many countries because of numerous severe cytochrome P-450/P-450-related drug interactions. Mibefradil was unique among calcium channel antagonists in that it blocks the T and L calcium channels

Fig. 1 Chemical structures of representative calcium channel antagonists, including the dihydropyridines, nifedipine and amlodipine; the benzothiazepine, diltiazem;

the phenylalkylamine, verapamil; the diarylamino compound, bepridil; and the tetrahydroisoquinoline, mibefradil.

Examples of the structures of these agents are shown in Fig. 1. All share the common property of antagonizing the slow, or so-called L-type, calcium channel. Further discussion of calcium channels follows in the pathophysiology section. Most of these agents have volumes of distribution greater than 2 L/kg, making clinically significant enhanced clearance of these drugs by extracorporeal techniques unfeasible. Exceptions are nifedipine (volume of distribution

0.64–1.4 L/kg) and possibly nifedipine (volume of distribution 0.6–2.21 L/kg) and nimodipine (volume of distribution 0.94–2.5 L/kg). However, because these and all other calcium channel antagonists are highly protein bound, they are not cleared to any significant degree by hemodialysis. Isolated case reports have shown conflicting results with the use of hemodialysis, charcoal hemoperfusion, and the molecular adsorbent recirculating system (MARS) [5].

Pharmacokinetics of Calcium Channel**Antagonists**

Volume of distribution: generally large*

Protein binding: extensive

Removal by extracorporeal techniques: minimal*

Mode of clearance: hepatic metabolism

Active metabolites: generally none[†]

*See text for exceptions.

[†]Verapamil and diltiazem have active metabolites, norverapamil and desacetyl diltiazem, respectively. These metabolites are significantly less active than are the parent molecules.

The pharmacokinetic features of calcium channel blockers vary. Moreover, it is difficult to estimate the half-life in an overdose situation, as the pharmacokinetics may be altered by the coingestants, presence of an ileus or decreased gut perfusion due to shock, or vasopressor administration. Pharmacobezoars have been reported, notably with certain formulations of extended release nifedipine [6–8]. In addition, calcium channel blockers are metabolized by the cytochrome P450 3A4 (CYP3A4) enzyme. In pharmacokinetic studies, coadministration of various inhibitors of this enzyme raised plasma calcium channel-blocker concentrations by up to 500% [9]. One well-conducted pharmacokinetic investigation of two cases of verapamil overdose found that despite markedly elevated plasma concentrations, the elimination of the parent drug and its primary metabolite, norverapamil, followed first-order kinetics, suggesting that their metabolism was not saturated during overdose [10]. However, despite the apparent first-order kinetics, the half-life of the elimination of verapamil was prolonged [11, 12].

Pathophysiology of Toxic Effects

Although there are a prodigious number of effects of calcium channel antagonists, the target organs of greatest importance to their clinical toxicity are the heart and the arterial vasculature. The effects of calcium channel antagonists on these two

organs differ among the various classes of agents (see Table 1). The selectivity of the various agents, in terms of their clinical effects, may derive from their tissue-dependent differential binding to L-type channels [12, 13]. Verapamil and diltiazem tend to bind nonselectively to vascular and cardiac tissue L-type calcium channels, whereas the dihydropyridine class binds primarily to L-type calcium channels in vascular tissue.

There are five different types of voltage-gated calcium channels, designated *L*, *T*, *P*, *Q*, and *N*. The L-type (or long lasting) channel is found primarily in the heart, arterial smooth muscle, and pancreatic beta cells, although it is present in a diverse group of other organs [14]. It is the largest channel and the slowest to undergo inactivation when opened—hence the designation *slow* calcium channel. The T-type (or transient) calcium channel is the fastest to become inactivated, and it is found on cardiac nodal and conducting cells. The P-type channel is found on cerebellar Purkinje cells. Q-type channels are similar to P channels. The N-type (or neuronal) calcium channel is found on neurons. The calcium channel antagonists inhibit calcium influx through the L-type channel, of which there are at least five subclasses.

Normally, there is an enormous concentration gradient of calcium across cell membranes, with serum concentrations in the millimolar range and an intracellular free calcium concentration of less than 10^{-7} M. The cell maintains this gradient by allowing calcium influx only through voltage-gated calcium channels, sequestering free calcium in the sarcoplasmic reticulum of muscle cells and maintaining an adenosine triphosphate (ATP)-driven calcium export pump (Fig. 2). When activated by membrane depolarization, the opening of the L-type channel results in an increase in the intracellular calcium concentration to the micromolar, or higher, range [16].

Pharmaceutical calcium channel antagonists act by binding to the α_{1c} subunit on the L-type calcium channel (Fig. 3). The exact binding site of the α_{1c} subunit for the various classes of calcium channel antagonists varies [14].

In cardiac myocytes or smooth muscle cells, the resulting increased intracellular calcium concentration initiates a cascade that results in muscle

Fig. 2 Ca^{2+} influx through the L-type (or slow) calcium channel results in excitation–contraction coupling in myocardial and arterial smooth muscle. *NKA* Na^+/K^+ -ATPase,

PL phospholamban, *SR* sarcoplasmic reticulum, *TT* T-tubule, *TnC* troponin complex (From [15])

concentration (see Fig. 2). This process is reversed by the active reuptake of calcium into the sarcoplasmic reticulum. In contrast to skeletal muscle, most of the calcium for cardiac myocyte or smooth muscle relaxation comes from an influx through the L-type calcium channel [17]. Calcium channel antagonists have little effect on skeletal muscle.

The L-type calcium channel is activated when phosphorylated by intracellular protein kinases (Fig. 4), which are stimulated by cyclic adenosine monophosphate (cAMP), the mediator of effects caused by agonism at cardiac β -receptors (see Fig. 35.2, ► Chap. 36, “Beta-Receptor Antagonists”). Phosphorylation of the calcium channel occurs with each depolarization. The site of phosphorylation is the regulatory subunit of the calcium channel, called *phospholamban* [16].

In contrast to cardiac myocytes, the nodal cell’s resting potential is due to a calcium gradient, not a sodium gradient. The spontaneous depolarization of the sinoatrial and atrioventricular nodes is due to slow calcium influx through L-type channels [18].

Cardiac Effects

Calcium channel antagonists affect both the myocardium and cardiac pacemaker cells. These effects are seen primarily with the phenylalkylamine and benzothiazepine classes of agents and less commonly as a result of the toxicity of the dihydropyridines. The effects of the cardioactive calcium channel antagonists are exerted on the cardiac pacemaker cells and on the

Fig. 3 Schematic L-type Ca^{2+} channel spanning the sarcolemmal membrane. The activation and inactivation gates control the flux of calcium through this channel. Binding sites for calcium channel antagonists, which decrease Ca^{2+} flux through the pore, are depicted. The actions of these

channels also are regulated by changes in electrochemical gradient across the sarcolemma. As shown in Fig. 4, the calcium channel can exist in open, resting, or inactivated states (From [15])

Fig. 4 Depiction of the three states of the calcium channel. In the open state, the activation and inactivation sites (see Fig. 3) are open. If either of these two sites is closed, the channel does not permit Ca^{2+} flux (From [15])

myocardium itself. As described earlier, cardiac pacemaker cells, such as those that make up the atrioventricular node, spontaneously depolarize as a result of a slow inward calcium flux. Inhibition of this calcium influx by calcium channel antagonists reduces the rate of pacemaker cell depolarization and, in cases of severe toxicity, can cause a complete arrest of this process [2].

The myocardium itself uses calcium through the action of voltage-dependent calcium channels that allow for calcium influx during phase II of the myocardial action potential, which is necessary for myocardial excitation–contraction coupling (see Fig. 2). The calcium influx that occurs at this time triggers further increases in intracellular free calcium concentrations by stimulating the sodium–calcium exchange pump on the myocardial cell membrane and by causing the release of stored sarcolemmal calcium. The combined result is a sharp increase in the intracellular calcium concentration, which leads to increased calcium binding to tropomyosin. Tropomyosin, a negative modulator of excitation–contraction coupling, acts by inhibiting the interaction of actin and myosin filaments. After calcium-induced activation of tropomyosin, the actin and myosin filaments are free to interact, causing muscle contraction. Inhibition of calcium influx results in decreased excitation–contraction coupling, which is manifested clinically by reduced cardiac inotropy.

Arterial Vasculature

In contrast to skeletal muscle and venous smooth muscle, arterial smooth muscle is highly dependent on external calcium for contraction. Calcium enters arterial myocytes via voltage-gated calcium channels, which, in a manner analogous to that in the heart, causes excitation–contraction coupling and increased arterial vascular tone. Inhibition of arterial smooth muscle calcium channels causes vasodilation. This effect is most evident with the dihydropyridine calcium channel antagonists (e.g., nifedipine).

Pancreatic Effects

Pancreatic insulin release is under the influence of the L-type calcium channel, which may become inhibited at high concentrations of channel blockers, thereby leading to hyperglycemia. A theoretical concern regarding hypoinsulinemia in patients with calcium channel antagonist poisoning is that in shock states the myocardium shifts its substrate preference from free fatty acids to glucose [19, 20]. Hypoinsulinemia adversely affects cardiac myocyte glucose uptake, which may be crucial to meeting its energy requirements under these conditions [21].

Metabolic Effects

Calcium channel antagonism can cause a decrease in mitochondrial calcium intake [20, 22], resulting in a reduction in pyruvate dehydrogenase activity and lactate accumulation [23]. This enzyme is required for pyruvate oxidation and subsequent Krebs cycle metabolism. Inhibition of pyruvate dehydrogenase causes hyperlactatemia.

Clinical Presentation and Life-Threatening Complications

Although there are major differences in the effects of the different classes of calcium channel antagonists when used therapeutically, some of these distinctions may be lost during overdose [24], wherein various pharmacologic actions tend to become clinically amplified. In general, the clinical presentation of calcium channel antagonist toxicity is one of hypotension, sinus node and myocardial depression, atrioventricular block, dysrhythmias, and hyperglycemia [25]. Other effects that commonly have been described with these agents are acute kidney injury, metabolic acidosis, and acute pulmonary edema [21, 25–29]. Effects of intoxication with these agents may be delayed (>6 h) and prolonged (>24 h) after the ingestion of sustained-release preparations [29].

Hypotension

In a prospective case series of 113 hospitalized patients with calcium channel antagonist overdose, hypotension (defined as systolic blood pressure <100 mmHg) was present in 43% of patients. Systolic blood pressure less than 60 mmHg was reported in 8% (nine) of patients [27]. Hypotension can be caused by either decreased peripheral resistance or cardiac pump failure in all calcium channel antagonists [24]. Other parameters of tissue–organ hypoperfusion (e.g., urine output, acid–base status) should be monitored closely in these patients.

Cardiac Conduction Deficits

Sinus node depression, all degrees of heart block, and junctional rhythms have been reported after calcium channel antagonist intoxication, more frequently after verapamil or diltiazem overdoses [29]. Most often, these conditions resolve within the first 48 h, but they have been reported to persist for 7 days [27, 30].

Cardiac Dysrhythmias

In the major series addressing cardiac dysrhythmias, bradycardia has been reported to occur in 29% of verapamil and diltiazem overdoses and in 14% of nifedipine overdoses. One-half to two-thirds of patients poisoned with the former two agents had heart rates less than 40 beats/min. There were no such cases reported in the same series in nifedipine-poisoned patients [27].

Sinus tachycardia is a common feature of poisonings by vasodilating (primarily dihydropyridine) calcium channel antagonists, occurring in one series in 57% of nifedipine overdoses, 26% of diltiazem overdoses, and 18% of verapamil poisonings [27]. Tachycardia also has been reported in several case reports of amlodipine overdose [31, 32], possibly secondary to carotid sinus reflex stimulation.

Noncardiogenic Pulmonary Edema

Although it is the impression of medical toxicologists that severe calcium channel antagonist poisoning may be accompanied by noncardiogenic pulmonary edema, the true incidence of this complication has not been formally studied, and documentation of its occurrence exists primarily in the form of case reports [33–37]. Several of these cases may in fact represent cardiogenic pulmonary edema related to aggressive fluid resuscitation in patients who have calcium channel antagonist-induced pump failure. However, there has been little published documentation of hemodynamic parameters, such as cardiac output, cardiac index, or pulmonary capillary wedge pressure, in these patients. It is hypothesized that dilation of a prepulmonary capillary or a drug-induced change in alveolar membrane permeability may contribute to noncardiogenic pulmonary edema [38–41].

Diagnosis

The determination of calcium channel antagonist toxicity generally starts with a history of the ingestion of these substances. In the absence of such a history, suspicion of toxicity by these medications should arise in a patient who presents with hypotension and other signs of toxic effects of these agents, as described earlier, which may be complicated by the diversity of presentation provoked by the different classes and pharmacokinetic formulations of agents. It is important to note that serum glucose concentrations correlate directly with the severity of verapamil and diltiazem intoxications. In fact, in a retrospective study conducted by Levine et al., the percentage increase of the peak glucose concentration was a better predictor of severity of illness than hemodynamic derangements [42]. In addition, Megarbane et al. have shown that a verapamil cutoff point of 5.0 μ M (2.2 ug/ml) was 100% sensitive and 91% specific to show a 2.76-times increase in the odds of fatality [43]. However, quantitative calcium channel antagonist determinations are generally available only from

commercial reference laboratories, and routine drug screens typically do not detect calcium channel antagonists.

Calcium channel antagonists generally are not considered to be radiopaque, although one case report has suggested that sustained-release verapamil may be detected radiologically [44]. Another case report of a fatal overdose with a sustained-release verapamil preparation found a large concretion of this material at autopsy, although it was not seen in abdominal radiographs obtained before death [45].

Treatment

As with all serious poisonings, the initial approach to the treatment of patients who ingested a potentially toxic amount of a calcium channel antagonist should be focused on preventing toxicity, maintaining adequate airway ventilation, oxygenation, and hemodynamic support. Based on the evidence documented in a systematic review [5] that predated the establishment of a working group, in 2015 representatives from 12 international critical care, emergency medicine, and toxicology associations proposed a stepwise approach for the in-hospital treatment of calcium channel-blocker poisoning (see Fig. 5) [46]. This section will discuss the treatments considered at each step, as well as other therapies that have been studied, but that are not included in these recommendations.

Asymptomatic Patients

It is recommended to observe asymptomatic patients who ingested a potentially toxic amount of a sustained-release calcium channel antagonist for approximately 24 h and to intervene with other treatments if they develop signs of toxicity (level II-3 evidence) [47]. No specific recommendation has been made by the international working group concerning decontamination. Activated charcoal may be efficient to prevent or decrease toxicity if it is administered soon after ingestion (level II-3

evidence) [48, 49]. However, there are no studies that indicate that the administration of activated charcoal significantly alters the outcome in these patients. The administration of activated charcoal should be done with great caution in patients who may develop alterations in mental status or seizures secondary to their ingestions.

Gastric lavage [50–52] or whole-bowel irrigation [53–55] are not recommended by the authors. Some hemodynamically unstable patients may not tolerate the vagal stimulation induced by the two latest decontamination modalities. Moreover, in a human volunteer study of sustained-release verapamil ingestion, whole-bowel irrigation did not reduce drug absorption significantly [51].

Symptomatic Patients: First-Line Treatments

Because these patients may have depressed mentation or evolving pulmonary edema, serious poisonings with these agents often warrant endotracheal intubation and mechanical ventilation. Intubation and mechanical ventilation is warranted in the presence of cardiovascular dysfunction requiring significant doses of pressors. Close monitoring of cardiac rhythm, vital signs, respiratory status, and urine output is fundamental to intensive care unit (ICU) management.

Indications for ICU Admission in Calcium Channel Antagonist Poisoning

Patient is mechanically ventilated or is anticipated to require it.

Hemodynamic instability is anticipated to become unstable.

Hyperglycemia of 188 mg/dL or more.

Coingestions requiring ICU care.

Because some of the manifestations of calcium channel antagonist intoxication may be caused by different mechanisms, additional monitoring and diagnostic modalities may be indicated. Hypotension caused by these poisonings may be the result of either decreased cardiac

Fig. 5 Treatment algorithm suggested by an international working group building recommendations for the treatment of calcium channel-blocker poisoning [46]

output, systemic vascular resistance (SVR), or both. Therefore, it is preferable to assess myocardial function with a bedside echocardiogram or with more invasive hemodynamic monitoring techniques to identify the etiology of hypotension, to choose the appropriate therapeutic modalities, and to monitor the efficacy of these treatments (level III evidence). Fluid administration should also be titrated based on the patient's response (level III evidence).

As a first-line treatment in symptomatic patients, the international working group recommends the use of calcium IV, high-dose insulin, vasopressors such as norepinephrine or epinephrine, and to consider dobutamine if the patient presents with cardiogenic shock, or atropine if the patient presents with bradycardia [46].

Calcium (Level II-3 Evidence)

Given that the fundamental pathophysiology of calcium channel antagonist toxicity is an inhibition of calcium flux into target tissues, it seems intuitive that calcium supplementation would be an effective treatment, and to a significant degree, relevant data bear this out. The majority of animal studies using calcium demonstrated a reduced mortality, as well as hemodynamic improvement. However, not every patient predictably responded to calcium in human case series and case reports [5]. It is likely that patients who are severely poisoned and patients in whom therapy is started late constitute the population that may be refractory to calcium therapy of their hypotension [56]. Insufficient doses of calcium are another potential explanation for apparent nonresponders [57].

Calcium concentrations typically are expressed in mg/dL or mmol/L; 1 mg/dL is equivalent to 0.25 mmol/L. Because calcium is a divalent cation, 1 mmol is equivalent to 2 mEq. The use of calcium chloride (CaCl_2) in the treatment of calcium channel antagonist toxicity is preferable to calcium gluconate because the former has approximately three times the molar calcium concentration of the latter. There are 13.6 mEq (or 270 mg) of calcium in 10 mL of 10% CaCl_2 compared with 4.6 mEq (90 mg) in an equivalent ampule of calcium gluconate; 10 mL of 10% CaCl_2 or calcium gluconate contains 1 g of the respective salt. The 13.6 mEq/L of CaCl_2 means that calcium constitutes 27% of the chloride versus 9% in the 4.6 mEq of calcium gluconate.

There are no uniformly accepted infusion protocols for calcium administration in this setting. In a systematic review looking at treatments for calcium channel-blocker poisoning [5], the dose employed was typically an intravenous (IV) single dose of calcium chloride (1–5 g), sometimes followed by an infusion, or the equivalent dose in calcium gluconate. The international working group proposed 0.1–0.2 mL/kg of calcium chloride 10% IV Q10–20 min or an infusion of 0.2 mL/kg/h [46]. Adverse effects, such as hypercalcemia, were rare. Nevertheless, patients who are receiving calcium infusions should be monitored for hypotension, bradydysrhythmias, and conduction disturbances, and it may be imprudent to allow the ionized calcium to exceed 2 mmol/L [58]. Because of the caustic nature of CaCl_2 , it is preferable that it be administered through a large and ideally central line.

High-Dose Insulin (Level II-2 Evidence)

Three mechanisms of action have been proposed for high-dose insulin: (1) it increases inotropy by enhancing coronary blood flow (without increasing oxygen requirements) and by improving calcium handling and glucose transport, (2) it increases intracellular glucose transport by affecting phosphatidylinositol 3-kinase (a major insulin intracellular signaling pathway), and (3) it decreases vascular resistance by increasing endothelial nitric oxide synthase activity

[59]. Therefore, insulin is a potential inotrope, particularly when the myocardium is depressed [60, 61]. Normally, free fatty acids are the preferred myocardial energy substrate. In a canine model of verapamil toxicity [19], the change in myocardial preference for carbohydrates as an energy substrate is accompanied by the development of relative insulin resistance [62, 63]. After supplemental insulin infusion, the suppressed phosphodiesterase III activity was enhanced, preventing lactate formation and allowing for more efficient myocardial carbohydrate use to meet the demand for ATP production.

Insulin also enhances the influx of potassium into the intracellular space, causing hypokalemia and prolonging phase II of the myocardial action potential. During phase II, there is a calcium influx, and the prolongation of this phase increases intracellular calcium concentrations, promoting increased contractility [64]. In this way, the hypokalemia associated with insulin administration may be beneficial, and it has been suggested that it should not be treated unless it is severe [21].

High-dose insulin (IV bolus of 1.0 unit/kg followed by a 0.5–2.0 unit/kg/h infusion) resulted in an improvement in hemodynamics in one of two human observational studies, all five human case series, and in all four animal studies reported in a systematic review, but only animal studies could demonstrate a survival benefit [5]. Therefore, the international working group recommended a bolus of 1 U/kg followed by an infusion of 1 U/kg/h as a single therapy in the presence of myocardial dysfunction or even in the absence of documented myocardial dysfunction if used in combination with fluids, calcium, and vasopressors [46]. Euglycemia should be maintained with dextrose infusion if needed. Considering that incremental doses of high-dose insulin up to 10 U/kg/h are supported by little evidence [65], the international working group suggested this regimen only for patients with evidence of myocardial dysfunction who do not respond to first-line therapies or as a rescue treatment [46]. Based on these recommendations, we suggest a more detailed regimen to initiate, maintain, and terminate the high-dose insulin regimen (Table 2).

Table 2 Suggested regimen for high-dose insulin therapy

Set up D ₅₀ IV ^a (D ₂₅ for small children ^a)
Treat initial hypokalemia, if present
Rapid bedside capillary blood glucose determination. If <200 mg/dL (11 mmol/L):
<i>Adults:</i> administer bolus of 25 g of glucose (50 mL D ₅₀)
<i>Small children:</i> administer bolus of 0.25 g/kg of glucose (1 mL/kg)
Prepare 1 U/mL IV solution of regular insulin
Give initial insulin bolus of 1 U/kg insulin IV
Followed by an infusion of 1 U/kg/hr
Adjust infusion rate based on hemodynamical response
Rapid bedside capillary blood glucose determination at least after 0.5 hour and hourly thereafter
Infuse D ₅₀ (D ₂₅ for small children) at a rate such that blood glucose is maintained in the 150–200 mg/dL range (5.5–11 mmol/L)
Determine serum potassium concentrations hourly for at least 4 hr and then every 2 hr if it has been stable
Continue high-dose insulin therapy until vasopressors are weaned off
If incremental doses of high-dose insulin (level II-3 evidence) is considered:
Concentrate the regular insulin solution (10 U/ml) to avoid fluid overload
Titrate the insulin infusion by 1–2 U/kg/h every 15 min up to 10 U/kg/h based on the hemodynamical response
Rapid bedside capillary blood glucose determination at least every 0.5 hr when titrating up or down and hourly thereafter
Infuse D ₅₀ (D ₂₅ for small children) at a rate such that blood glucose maintained in the 150–200 mg/dL range (5.5–11 mmol/L)
Determine serum potassium concentrations hourly during titration and then every 2 hr if it has been stable
When the patient is improving hemodynamically and the glycemia is decreasing, titrate down the insulin infusion to 1 U/kg/h
Continue high-dose insulin therapy until vasopressors are weaned off

D₅₀ 50% dextrose, D₂₅ 25% dextrose

^aPreferentially in a central line because of its high concentration

Hypoglycemia and hypokalemia were reported as adverse effects [5]. In the series by Yuan and coworkers [21], the mean maximal dextrose requirement was 28.4 g/h (range 10–75 g/h). A total of 100 mL of 50% dextrose solution contains 50 g of glucose. Because of its osmolar effects at

this concentration, dextrose infusion in this setting should be administered through a central venous line. Given the hyperglycemia that may occur as an associated effect of calcium channel antagonist intoxication, not all patients receiving insulin therapy require dextrose supplementation [66, 67].

The clinical pharmacology of high-dose insulin therapy is discussed in greater detail in ► Chap. 147, “Euglycemic Insulin Therapy.”

Norepinephrine or Epinephrine (Level II-3 Evidence)

Vasopressors and inotropes constitute a diverse group of agents, consisting primarily of vasopressin, phenylephrine, norepinephrine, epinephrine, dopamine, dobutamine, isoproterenol, and milrinone. Each has its unique physiologic properties, which render it potentially useful under various clinical circumstances. Ideally, it is advantageous to determine whether the hypotension after calcium channel-blocker intoxication is due to myocardial depression or vasodilation. In a systematic review, norepinephrine infusion showed improved survival and hemodynamics in animal studies and case series [5]. Epinephrine was associated with increased cardiac output in animal studies, but hyperglycemia and increasing lactate were noted as adverse effects [5]. Therefore, the international working group recommended the use of norepinephrine and/or epinephrine in the presence of shock and preferentially norepinephrine in the presence of vasodilatory shock [46]. To be noted, Levine et al. reported a maximal infusion rate up to 100 µg/min for norepinephrine and 150 µg/min for epinephrine without significant ischemic complications [68]. Dopamine was not suggested by the international working group, as it yielded variable results [46].

Other Vasopressors and Inotropes

Patients with myocardial depression seem to benefit most from agents with β-adrenergic activity, such as dobutamine (level II-3 evidence) [46]. However, given the risk of hypotension, this therapy would not be suggested in other circumstances [68]. Isoproterenol, the most potent

β -agonist of this group, has been used successfully in animal models [69], although evidence for its efficacy in humans is only anecdotal. There is concern for the arrhythmogenic and myocardial ischemic effects of isoproterenol. Inamrinone is an inhibitor of phosphodiesterase III that is thought to prevent the degradation of cAMP, theoretically resulting in an enhanced flux of calcium into the cell. The inhibition of this enzyme may be insufficient, however, to increase cAMP concentrations above the threshold required for an inotropic myocardial response [70], and there is the theoretical concern that because inamrinone may upregulate the dihydropyridine receptor, the potential for antagonism of the calcium channel is increased [71]. Animal studies have shown variable results [72–76].

Patients with significantly reduced SVR may benefit from the α_1 -agonist actions of norepinephrine [5]. However, in one animal study of calcium channel antagonist intoxication, increasing SVR with phenylephrine, a pure α_1 -agonist, appeared to worsen myocardial depression by increasing afterload [77]. Vasopressin was also reported as potentially harmful in one blinded, randomized controlled trial using a swine model of verapamil poisoning [78], although one case series of two patients [79] and one case report [80] showed blood pressure improvement when added to other vasopressors.

In summary, concerning the use of vasopressors and inotropes, the international working group recommended the use of norepinephrine and epinephrine for the treatment of calcium channel-blocker poisoning and considered the use of dobutamine if the patient presents with cardiogenic shock. To be noted, atropine is also considered as a first-line treatment if the patient presents with bradycardia, considering that the systematic review revealed occasional improvements [46].

Symptomatic Patients: Refractory to First-Line Treatments

In cases refractory to first-line treatment, the international working group suggested the use

of incremental doses of high-dose insulin, up to 10 U/kg/h, as described previously in patients presenting with myocardial dysfunction [46]. In patients presenting with bradycardia or high-grade atrioventricular block, the working group suggested the use of a pacemaker [46]. Lipid emulsion therapy was also suggested [46].

Cardiac Pacing (Level II-3 Evidence)

Cardiac pacing has been reported to be effective in patients with bradydysrhythmias induced by calcium channel antagonists [27, 81]. However, it has been reported in some patients with high-degree atrioventricular nodal block that pacemaker capture may not occur [27]. Therefore, the international working group proposed trying transcutaneous pacing attempts first to avoid spending time on a therapy that involves risk and may not be effective [46].

Lipid Emulsion (Level II-3 Evidence)

Concerning the use of lipid emulsion therapy, it is hypothesized that this creates a separate intravascular compartment within which lipophilic drugs are sequestered from their sites of action [82]. This treatment also provides fatty acids that may be used by the myocardium and may increase intracellular calcium [83].

In animal models of IV verapamil toxicity and several case reports, the administration of a 20% lipid emulsion was associated with improvement in hemodynamics and survival [5]. However, there was no significant improvement or an increased mortality in two animal studies using an oral verapamil toxicity model (abstract available only) [84, 85]. In one case report [86], adverse effects, such as hypertriglyceridemia and hypoxemia, were observed with lipid emulsions when used at exceptionally high doses (2 L). Hyponatremia, extreme lipemia, and an inability to obtain reliable complete blood count, arterial blood gas, or electrolyte levels were also noted. The most commonly recommended dose is 1.5 mL/kg of 20% lipid emulsion administered as a bolus, repeated up to two times, as needed, until clinical stability is achieved, followed by an infusion of 0.25 mL/kg/min for 30–60 min [87].

The clinical pharmacology of lipid emulsion therapy is discussed in greater detail in ► [Chap. 152, “Lipid Resuscitation Therapy.”](#)

Symptomatic Patients: Refractory Shock or Peri-arrest

In refractory shock or peri-arrest patients, the international working group recommended the use of incremental doses of high-dose insulin, up to 10 U/kg/h, and lipid emulsion therapy, as previously described, if not already tried. In the presence of myocardial dysfunction, the working group members also added the consideration of extracorporeal life support in centers where the therapy is available.

Extracorporeal Life Support (Level II-3 Evidence)

In an observational study conducted by Masson et al., extracorporeal life support was associated with a lower mortality when initiated in a group of 14 patients compared with conventional therapies provided to a group of 48 patients (48% vs. 86%, respectively) after adjustment for the Simplified Acute Physiology Score (SAPS) II and beta-blocker intoxication [88]. Most human case series reported positive functional outcomes in the majority of survivors, but some patients experienced limb ischemia, thrombosis, or hemorrhage [89–91]. It is important to note that a Canadian cost-effectiveness analysis assessing the use of this therapy in patients in shock or cardiac arrest secondary to cardiotoxicant poisoning concluded that cost was not an argument against providing extracorporeal life support in centers where the therapy is available [92].

Patients in Cardiac Arrest

For a patient who sustains a cardiac arrest, the pathophysiologic changes induced by calcium channel antagonists are potentially completely reversible despite prolonged resuscitations, as exemplified by one patient who was in cardiac

arrest for 2.5 h and recovered fully [93, 94]. A patient in cardiac or circulatory arrest should be treated aggressively using calcium IV (level II-3 evidence) and lipid emulsion therapy (level II-3 evidence) in addition to standard advanced cardiac life support. [46] The use of extracorporeal life support should also be considered in centers where the therapy is available (level II-2 evidence) [46].

Other Treatments

Glucagon

Glucagon is a 29-amino acid polypeptide hormone secreted by pancreatic beta cells. It has a molecular weight of 3485 daltons (Da), and its volume of distribution is 0.04 L/kg. Well known for its biologic actions of increasing blood glucose and glycogenolysis, glucagon is also a potentially powerful cardiac inotrope and chronotrope [95, 96], acting at specific cardiac G protein-coupled receptors [97]. When bound to its receptor, glucagon stimulates an increase in cAMP, which leads to an increase in myocardial calcium influx [98, 99].

A study in isolated rat hearts, using a Langendorff preparation poisoned with various calcium channel blockers, showed that glucagon can reverse the depression of the rate of pressure change in the ventricle, dP/dt, by these agents. A clinically achievable serum glucagon concentration of 0.5 mmol was required [99]. Similarly, several animal studies with rodents [72, 100] and dogs [60, 77, 101, 102] reported that glucagon reverses verapamil-induced bradycardias. However, four of five studies employing canine models of verapamil intoxication failed to show a beneficial effect of glucagon on mean arterial pressure [60, 101–103]. Only one of the three human case series documented by the systematic review reported clinical improvement, and side effects, such as hyperglycemia and vomiting, have been reported [5]. Based on variable effects, possible side effects, and the availability of more effective alternatives, the international working group suggested not to use glucagon in calcium channel-blocker poisonings [46].

Methylene Blue

Case reports of amlodipine poisoning describe hemodynamic improvement after the administration of methylene blue (1–2 mg/kg bolus followed by infusions) [104–106]. In amlodipine poisoning, vasodilation occurs through the stimulation of nitric oxide release with increased cyclic guanosine monophosphate (cGMP) production. Methylene blue inhibits guanylate cyclase, the enzyme responsible for the production of cGMP, and it also has the ability to scavenge nitric oxide, as well as to inhibit nitric oxide synthase [105]. However, this therapy has only been documented by case reports thus far.

Other Therapies

As underlined by the systematic review published in 2014 [5], the use of 4-aminopyridine, levosimendan, L-carnitine, plasma exchange, albumin dialysis, charcoal hemoperfusion, continuous venovenous hemodiafiltration, intra-aortic balloon pump, left ventricular assist devices, and an Impella have been reported in humans without sufficient positive evidence available to recommend these interventions. The use of bay K8644, CGP28932, cyclodextrin, sugammadex, liposomes, fructose 1,6-diphosphate, PK11195, triiodothyronine, digoxin, and bicarbonate has only been studied in animals [5].

Criteria for ICU Discharge in Calcium Channel Antagonist Poisoning

No requirement for mechanical ventilation
Stable hemodynamic status

Special Populations

Pediatric Patients

There have been two retrospective case series of pediatric calcium channel antagonist ingestions. One involved only 29 cases [107]. The second study comprised 283 patients with a mean age of 27 months (range 8 months to 6 years) [48]. The first study called attention to the potential

seriousness of sustained-release calcium channel antagonist ingestions in children. In the larger study, 61% of the cases involved this type of formulation. Even the larger study by Belson and colleagues [48] is limited, however, in the amount of information available, as it was simply an analysis of data available to one poison control center over a 6-year period. Much about patient history, presentation, and clinical course is unknown. Little information can be gleaned about therapeutic options in children based on these studies, and in the absence of other data, they should be treated in the same fashion as adults. However, in the absence of evidence that children respond differently than adults to CCB poisoning, it may be reasonable to apply adult recommendations to the pediatric population.

Common Errors in Calcium Channel Antagonist Poisoning

Resorting to whole-bowel irrigation or gastric lavage despite its lack of documented efficacy for reducing calcium channel antagonist absorption

Failing to recognize when invasive hemodynamic monitoring is indicated

Administering fluids despite the absence of fluid responsiveness

Discontinuing high-dose insulin therapy when the patient is hypoglycemic, but is still hemodynamically unstable

Key Points in Calcium Channel Antagonist Poisoning

1. Calcium channel antagonists induce a syndrome primarily characterized by
Hypotension
Bradycardia and cardiac conduction disturbances
Hyperglycemia
2. The above triad may not be present in all patients.
3. Presentations may be delayed with sustained-release preparations.

(continued)

4. Treatment options are the following:
 - First line: fluids, calcium IV, high-dose insulin, norepinephrine/epinephrine, dobutamine if in cardiogenic shock, and atropine if bradycardia is present.
 - When refractory to first-line treatments: incremental doses of high-dose insulin, lipid emulsion therapy, and cardiac pacing if bradycardic.
 - When refractory shock or peri-arrest: consider extracorporeal life support if evidence of myocardial dysfunction.
 - In cardiac arrest: administer calcium IV and lipid emulsion therapy in addition to standard advanced cardiac life support and initiate extracorporeal life support in centers where the therapy is available.
5. Calcium channel blockers are not removed effectively by hemodialysis.
6. Be vigilant for ischemic complications that may result from protracted hypotension and its treatment.

The medical use of cardiac glycosides began in 1785 with the publication of Withering's monograph on the therapeutic efficacy and toxicity of the leaves of the common foxglove plant, *Digitalis purpurea*. Various glycosides including digitoxin and ouabain were then extracted from plants, and digitalis glycosides have been widely prescribed for more than 230 years.

Digitalis still remains an important and useful therapy for patients with heart failure and/or atrial fibrillation [1]. However, despite a pertinent contribution of their pharmacological properties combining positive inotropic and negative chronotropic effects to reduce symptoms and hospital admissions in heart failure patients, meta-analyses showed neutral effect on all-cause mortality and robust trial data are lacking in patients with atrial fibrillation [2, 3]. Following the availability of therapies providing proved prognostic benefits in these patients including angiotensin-converting enzyme inhibitors, beta-blockers, aldosterone antagonists, and cardiac resynchronization therapy, prescription rates of digoxin have fallen substantially [4]. Their use is now restricted to the treatment of heart failure due to reduced ejection fraction with or without supraventricular dysrhythmias including atrial fibrillation.

Digitalis poisoning may result from either acute suicidal massive ingestion or more frequently from chronic toxicity in patients with cardiac diseases and renal failure. Digitalis overdose may lead to life-threatening toxicity. In 1976,

Fig. 1 Chemical structure of digoxin. Digitoxin lacks a hydroxyl group on the C ring, resulting in greater lipophilicity

Smith and colleagues reported the first case of human digoxin poisoning treated with anti-digoxin-specific Fab fragments, unveiling the modern era of treatment of cardiac glycoside toxicity [5].

Biochemistry of Digitalis Glycosides

Cardiac glycosides of therapeutic interest share a common steroid nucleus structure with one or more glycosidic residues bound at its C3 (Fig. 1). Their potent and selective properties to inhibit the membrane Na^+/K^+ -ATPase are due to the β -hydroxyl group at its C14 and the unsaturated lactone at its C17. Removal of the glycoside moieties (forming the genin or aglycone part) only minimally affects their pharmacological properties. The absence of a hydroxyl group at the C12 of the nucleus distinguishes digitoxin from digoxin. In addition to foxglove (*Digitalis*), other cardiac glycosides are divided in two subclasses, the cardenolides and the bufadienolides [6]. Cardenolides are present in *Antiaris toxicaria* (antiarin), *Nerium oleander* called common oleander (oleandrin, folinerin, adynerin, digitoxigenin), *Thevetia peruviana* called yellow

oleander (thevetin A and B, peruvoside, neriifolin, thevotoxin, ruvoside, and theridoside), *Cerbera odollam* called sea mango (cerberin), *Convallaria majalis* called lily of the valley (convallarin, convallamarin, and convallatoxin), and *Strophanthus* sp. (ouabain). Bufadienolides are present in *Urginea maritima* called red squill (scilliroside and proscillaridin A, scillarene A, scilliglaucoiside, and scilliphaeoside) and *Rhinella marina* called cane toad (bufalin, manrinobufagenin, and telocinobufagin). An ouabain-like compound (resibufogenin) is also found in the skin of the bufo toad (*Bufo* spp.). Neriifolin, cerberin, and cerberigenin, contained in the fruit kernel of the red-eye-sea mango tree *Cerbera manghas* L. on which the coconut crab *Birgus latro* L. feeds, are the toxic agents leading to cardenolide poisoning when eating this kind of crab.

Pharmacology and Mechanisms of Toxicity

Digitalis reversibly inhibits the membrane-bound alpha subunits of the Na^+/K^+ -ATPase pump in cardiac, smooth, and skeletal muscles and lungs

and kidneys [1, 7, 8]. By increasing the intracellular sodium concentration in cardiomyocytes, digitalis promotes activity of the $\text{Na}^+/\text{Ca}^{2+}$ -exchanger, thus enhancing the intracellular calcium concentration which is taken up by the sarcoplasmic reticulum. This action directly results in the greater interaction between the myocardial contractile proteins, increasing the force of cell contraction and improving the left ventricular systolic function. Consistently, the intravenous digitalis administration results in the immediate evidence of significant increase in stroke index, cardiac output, left ventricular ejection fraction, exercise tolerance, and decrease in pulmonary capillary wedge pressure [9]. Within the central nervous system, digitalis-mediated Na^+/K^+ -ATPase also reduces the heart rate, by exerting a parasympathomimetic action on the sinoatrial and atrioventricular nodes, slowing their conduction and increasing the refractory period. Additionally, digitalis is responsible for vagal activation shifting the autonomic balance toward parasympathetic dominance. By reducing plasma norepinephrine, digoxin modulates the initially compensatory but finally detrimental neurohormonal activation observed in heart failure patients. This direct anti-sympathetic activity likely reflects the attenuation and sensitization of the augmented baroreflex in heart failure patients with raised filling pressures. Taken together, the pharmacological ability of digitalis to simultaneously increase cardiac inotropy and constrain cardiac chronotropy is unique. Digitalis increases vagal tone and decreases sympathetic activity. The plasma concentration and type of digitalis clearly determine which mechanism predominates. These mechanisms of action are common to all cardiac glycosides, although largely described using digoxin and ouabain; however, differences exist among the glycosides and influence the toxicity and the therapeutic response. Consistently, insulin reverses the effects of digoxin but not ouabain on Na^+/K^+ -ATPase due to their binding to different sites. Similarly, pharmacokinetics highly varies according to the digitalis molecule (Table 1).

In overdose, digitalis-related Na^+/K^+ -ATPase inhibition may result in excessive intracellular

Table 1 Pharmacokinetics of digoxin and digitoxin

Digoxin
<i>Absorption:</i> mainly in the proximal small intestine, bioavailability of 80%
<i>Volume of distribution:</i> 5.6 L/kg; slow but widespread dissemination into the tissues, particularly the myocardium, kidneys, and skeletal muscle; duration of distribution (2–6 h)
<i>Protein binding:</i> 20–30%
<i>Active metabolites:</i> digoxigenin, digoxigenin monodigitoxiside and bis-digitoxiside
<i>Predominant elimination route:</i> kidney
<i>Elimination:</i> as unaltered in urine (93%)
<i>Elimination half-life:</i> mean 40 h, range 20–50 h
Digitoxin
<i>Absorption:</i> in the stomach (15%) and proximal small intestine (85%), bioavailability of >90%
<i>Volume of distribution:</i> 0.56 L/kg; rapid and widespread dissemination into the tissues due to its high lipophilic properties
<i>Protein binding:</i> 95%
<i>Active metabolites:</i> digoxin (minor pathway)
<i>Predominant elimination route:</i> liver (75–90%)
<i>Elimination:</i> as unchanged in the feces and urine
<i>Elimination half-life:</i> 4.9–8.1 days

Ca^{2+} increase resulting in a transient late depolarization (delayed afterdepolarization) accompanied by aftercontraction. Additionally, the increase in sympathetic activity accompanied by nonuniform increase in automaticity and vagal nerve-mediated depression of conduction in His-Purkinje and ventricular myocytes may cause life-threatening dysrhythmias.

Clinical Presentation and Life-Threatening Complications

Poisonings mainly result from pharmaceutical preparations of digitalis and more rarely from self-made preparations of cardiac glycoside-containing plants. Acute digitalis poisoning may result from accidental or suicidal exposure to a single elevated dose. Due to its narrow therapeutic index, chronic toxicity of digitalis has been reported in 6–23% of treated patients, particularly in the elderly [10, 11]. Several factors may alter patient's sensitivity to digitalis including acute

Table 2 Main predisposing and precipitating factors for digitalis toxicity

renal impairment and drug-drug interactions (Table 2) [10–17]. Macrolides, quinidine, verapamil, diltiazem, amiodarone, and others increase digoxin concentrations, mainly by competitions on their binding sites in tissues with a risk of digitalis toxicity.

Clinical and ECG Features

In the setting of acute poisoning, symptoms generally occur within 6 h of ingestion, but life-threatening symptoms may occur with delay, reflecting the relatively slow tissue distribution of digitalis. The noncardiac manifestations of digitalis toxicity are highly prevalent including gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal pain, and diarrhea), neurological symptoms (fatigue, weakness, hallucinations, delirium, and psychiatric disorders), and visual manifestations (scotoma, blurred vision, color aberration, and blindness). Mesenteric ischemia has been reported rarely. Physician should suspect digitalis toxicity and measure serum digoxin concentration in the onset of unexplained gastrointestinal, neurological, or visual manifestation in a digitalis-treated patient.

Digitalis-related cardiac toxicity results from the combination of conduction and rhythm disturbances [6]. Toxicity should be suspected when there is evidence of increased automaticity and depressed atrioventricular conduction. Flattening

or inversion of the T wave and depression of the ST segment related to long-term digitalis treatment should not be considered as toxicity criteria. The most common cardiac abnormality induced by digitalis is sinus bradycardia. Characteristic electrocardiogram (ECG) changes in the setting of digitalis overdose show dysrhythmias like atrial tachycardia, accelerated junctional rhythms, and fascicular tachycardia, as well as conduction disturbances like premature contractions of junctional or ventricular origin, sinoatrial block, and all degrees of atrioventricular blocks. In the chronic poisoning, the combination of atrial fibrillation and conduction disturbances is commonly observed resulting in irregular bradycardia. Onset of junctional tachycardia is highly suggestive too. Sinus arrest or exit block may occur. Ventricular ectopics and tachycardias are also reported and may be related to the underlying cardiac disease. Life-threatening arrhythmias primarily consist of third-degree atrioventricular block, ventricular tachycardia, and ventricular fibrillation. The contribution of the underlying cardiac disease including cardiomyopathy and coronary artery disease to digitalis toxicity is not clear [12].

When digitalis toxicity is suspected, kalemia and renal function should be urgently measured. Other electrolyte abnormalities should be interpreted in the onset of chronic digitalis poisoning according to concomitant conditions and medications.

Fatality and Prognosticators

Digitalis poisoning-attributed mortality rate ranged from 4.6% to 41% before the availability of anti-digoxin Fab fragments [18, 19] but remained between 6% and 29% after their availability [12, 15, 21]. Poor prognostic factors in acute digitalis poisoning were determined based on series of acute digitoxin poisoning and include age older than 55 years, male sex, hyperkalemia, and any degree of atrioventricular block (Table 3) [20]. Fatality rate significantly increases when serum potassium concentration is >4.5 mmol/L in the absence of adequate treatment. Ventricular dysrhythmias refractory to electrical

cardioversion are the leading cause of death (70%), followed by advanced atrioventricular block resulting in asystolic arrest (20%) and cardiac insufficiency causing multi-organ failure (10%). Rarely, death may result from mesenteric infarction.

Diagnosis

Diagnosis depends on whether digitalis poisoning is chronic or acute. Acute poisoning is typically straightforward. QT interval modifications are of diagnostic value only in patients not previously treated with digitalis. Diagnosis is confirmed by the measurement of the serum digitalis concentration. By contrast, in chronic poisoning, diagnosis is more difficult because noncardiac symptoms are nonspecific and some ECG abnormalities look like those related to the underlying cardiac disease. Thus, serum determination of digitalis concentration is the key step to assess the diagnosis and should be largely prescribed in cases of suspected digitalis intoxication, although digoxin toxicity occurs to date less frequently than historically reported.

The range of therapeutic (steady-state) concentrations of digoxin and digitoxin are

0.5–2.0 ng/mL (0.6–2.6 nmol/L) and 10–30 ng/mL (13–39 nmol/L), respectively. According to the various factors that may influence digitalis toxicity, no single serum concentration can definitively establish the presence or absence of toxicity [12]. Of 3434 serum digoxin concentrations assayed in 2009 patients, 320 (9.3%) were higher than the upper limit of the therapeutic range, but only 83 of the 138 patients evaluable for digoxin toxicity had clinical evidence of toxicity for an overall incidence of 4.1% [22]. In another retrospective study reporting 6133 digoxin concentrations measured in 5100 patients, only 13 among the 460 patients with serum digoxin concentration >2 ng/mL (>2.6 nmol/L) were diagnosed as digoxin overdose before obtaining the laboratory results [23]. Hospitalized patients with serum digoxin > 2.1 ng/mL (>2.7 nmol/L) spent a mean of 12.1 ± 17.1 days in hospital. The mean time to death for the patients who died was 5 ± 3.1 days. Two thirds of the patients who died in the hospital had increasing digoxin levels before death. In this study, renal failure was not significantly associated with increased mortality while serum digoxin concentration was. Mortality rate in patients with elevated digoxin concentrations and preexisting ECG abnormalities was 8% compared with 40% in patients with elevated

digoxin concentrations and new ECG abnormalities [23]. A fatality rate of 50% was reported in patients with digoxin concentrations > 6 ng/mL (7.7 mmol/L).

Serum potassium concentration significantly influences the toxicity associated with a given digitalis concentration [24]. In contrast to acute poisoning, most of the more serious arrhythmias found in patients with chronic toxicity are associated with serum potassium concentrations < 3.7 mmol/L [25]. An indication for transient pacemaker placement was present more frequently when digitalis intoxication was accompanied by hypokalemia (72%) than normokalemia (37%). In patients with digitalis intoxication-related dysrhythmias, normokalemic patients had a mean serum digoxin concentration of 6.68 ± 0.17 ng/mL (8.55 ± 0.22 mmol/L), whereas hypokalemic patients had a mean serum digoxin level of 1.13 ± 0.04 ng/mL (1.45 ± 0.05 mmol/L). Repletion of serum potassium sometimes corrected the dysrhythmia without significant changes in serum digoxin concentration. Hypomagnesemia likewise increases digitalis-related toxicity and may be a more frequent contributor to digoxin toxicity than hypokalemia [25]. Finally, prompt termination of the arrhythmias when stopping the drug administration or after infusing anti-digoxin-specific Fab fragments supports the diagnosis of chronic toxicity.

Management

Most cases of chronic toxicity are minor, and the patient may only require temporary withdrawal or reduction in his digitalis dosage on an outpatient or inpatient basis. However, more aggressive hospital treatment is sometimes mandatory to reduce the risk of death.

Gastrointestinal Decontamination

A single dose of activated charcoal (50 g) should be administered to all patients with acute ingestion of a potentially toxic exposure if ingestion occurred less than 2 h before. Although no clinical

trial confirmed its efficacy, this approach is based on the ability of charcoal to reduce digoxin peak in serum as well as on its safety (Grade III recommendation). There are insufficient clinical data to support or exclude the use of repeated doses of activated charcoal to enhance digitalis elimination [26]. Similarly, usefulness of gastrointestinal decontamination in chronically poisoned patients remains to be determined.

Extracorporeal Removal Techniques

The international EXTRIP work group published a systematic review and recommendations on the extracorporeal treatment for digoxin poisoning [27]. Based on data from 84 patients including six fatalities, they concluded that digoxin is slightly dialyzable (level of evidence = B) and that extracorporeal removal techniques are unlikely to improve the outcome of digoxin-toxic patients whether or not anti-digoxin Fab fragments are administered. Despite the lack of robust clinical evidence, they recommended against the use of extracorporeal removal techniques in cases of severe digoxin poisoning when Fab fragments were available (1D) and also suggested against the use of extracorporeal removal techniques when Fab fragments were unavailable (2D).

Indications for ICU Admission

All patients suspected of acute or chronic digitalis poisoning with symptoms, ECG or electrolyte abnormalities, or any other significant underlying morbidity should be admitted to the intensive care unit given the high fatality rate associated with digitalis poisoning. In contrast, clinically stable patients receiving digoxin who meet the following criteria:

- Mildly elevated serum digoxin concentrations
- Without signs and symptoms of digoxin toxicity
- With serum potassium > 3.7 mmol/L and < 4.5 mmol/L
- With no history of severe cardiac disease

are at low risk of developing serious digoxin toxicity and may not require treatment beyond the discontinuation of digoxin therapy.

Electrolyte Disorders

Correction of hypokalemia, hypomagnesemia, and dehydration is important in the presence of chronic toxicity. In chronically treated patients, hyperkalemia may result not only from digitalis toxicity but also from renal insufficiency and other medications (potassium-sparing diuretics, nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, and nonselective β -blockers) that should be withdrawn temporarily. In acute poisoning, hyperkalemia (>4.5 mmol/L) is the hallmark of severe toxicity, and the patient may thus require anti-digoxin Fab fragments. Calcium salts should be avoided since one major mechanism of digitalis toxicity is primarily calcium loading of the myocardium. In the presence of severe hyperkalemia (>5.6 mmol/L), glucose/insulin, sodium bicarbonate, and sodium polystyrene sulfonate enema may be started; but severe hypokalemia may result if anti-digoxin Fab fragments are simultaneously administered.

Non-antidotal Therapies

Atropine antagonizes cardiac glycoside vagal activation, increasing heart rate. Atropine is the first-line treatment of digitalis-induced sinus bradycardia or atrioventricular conduction disturbance [6, 28]. The therapeutic success of atropine is unpredictable because the more direct non-vagotonic cardiac effects of digitalis at toxic doses may predominate. Doses of 0.5–1 mg are recommended but higher doses up to 2–3 mg have been used for persistent bradycardia. However, the use of a large cumulative dose of atropine may lead to deleterious anticholinergic encephalopathy.

Antidysrhythmics, including phenytoin, lidocaine, procainamide, propranolol, and amiodarone, have been used to treat digitalis-

induced arrhythmias [29] (Grade II-3 evidence). Propranolol and procainamide must be avoided due to the risk of depression of cardiac conduction and contractility. Quinidine should not be used since it may prolong digoxin toxicity as a result of drug-impaired clearance. Lidocaine and phenytoin should be considered antiarrhythmic drugs of choice in the absence of anti-digoxin Fab fragments to treat digitalis-induced dysrhythmias because they have little effect on the sinus node and on AV conduction [7]. The role of fosphenytoin has not been evaluated in this setting.

Magnesium sulfate was effectively used to treat digoxin-induced arrhythmias, even in patients with normal or slightly elevated serum magnesium concentrations [30–32] (Grade II-3 evidence). Magnesium potentiates the activity of Na^+/K^+ -ATPase without altering digoxin binding. A decrease in serum potassium concentration after magnesium therapy is obtained, but adverse effects from hypermagnesemia, particularly in patients with impaired renal function, may be observed. Hypermagnesemia is unlikely to occur with an initial 10–20 mmol magnesium bolus, but is a real issue with infusion or repeated doses. Anti-digoxin Fab fragments are the most effective and safe antidysrhythmic strategy to prevent and reverse digitalis-induced life-threatening arrhythmias.

Transvenous or transcutaneous cardiac pacing may be used to correct digitalis-induced bradycardia or conduction disturbances and to prevent ventricular dysrhythmias [33]. Retrospective studies have suggested that pacing does not significantly decrease the mortality rate of acute digitalis intoxication [33, 34]. Given the high rate of nonfatal and fatal complications associated with cardiac pacing in acute digitalis toxicity, electrical cardioversion is potentially hazardous, and Fab fragment therapy should be considered first-line treatment.

Anti-digoxin-Specific Fab Fragments

The efficacy and safety of anti-digoxin-specific Fab fragments have been consistently reported in

adults [11–17, 21] and children [35–39] as well as in acute and chronic poisonings (Grade I evidence). A cost-effectiveness analysis supported the use of Fab fragments in the treatment of digoxin toxicity [40]. According to their cross-reactivity, Fab fragments can effectively neutralize digoxin, digitoxin, methyl-digoxin, β -acetyl-digoxin, lanatoside, ouabain, proscillaridin, and scilliroside and cardiac glycosides contained in yellow oleander and in toad and crab venom [41–46]. Anti-digoxin Fab fragments are indicated, based on internationally accepted criteria, to treat patients who present life-threatening tachy-bradyarrhythmias, hyperkalemia (>6 mmol/L), or hemodynamic instability with an elevated digoxin concentration (>2 ng/mL or 2.6 nmol/L) [47].

The theoretical maximum dose of anti-digoxin Fab Fragments is the one required to neutralize the body burden of digitalis. This dose can be calculated using either the supposed ingested dose or the serum digitalis concentration (Table 4). When no data are available regarding the presumed ingested dose or the plasma concentration, empirical dosing recommendations are to administer 400–800 mg of Fab (closely equivalent to 10–20 vials of DigiFab[®]) in acute toxicity and 120–240 mg of Fab (3–6 vials of DigiFab[®]) in chronic toxicity.

However the necessity of administering an equimolar dose of anti-digoxin Fab fragments to obtain an initial beneficial response is not supported by the literature [12, 21, 47]. The calculation of the equimolar dose of Fab fragments based on either the estimated ingested dose or the serum digitalis concentration frequently overestimates the amount of digitalis in the body. The calculation based on the estimate of ingested dose uses only the theoretical bioavailability of cardiac glycosides, whereas during the time interval between ingestion of digitalis and Fab administration, a fraction of the dose of digitalis has been already eliminated [48]. The relationship between the serum digitalis concentration and the corresponding actual amount in the body should also be questioned in patients admitted early during the course of the acute poisoning, since it is only accurate during the drug

Table 4 Calculation of dosage of Fab fragments from body load of digitalis

From the ingested amount, if the amount and type of digitalis are known:
$Q = IA \cdot A$
Q = body load of glycoside (mg)
IA = ingested amount of glycoside (mg)
A = digoxin bioavailability (0.6) or digitoxin bioavailability (1)
From the serum glycoside concentration, if the steady-state serum concentration is known:
$Q = SGC \cdot Vd \cdot Wt \cdot 10^{-3}$
Q = body load of glycoside (mg)
SGC = serum glycoside concentration (ng/mL)
Vd = distribution volume: 5.61 L/kg (digoxin) or 0.56 L/kg (digitoxin)
Wt = patient weight (kg)
Conversion factors: $SGC \text{ (nmol/L)} \times 0.781 = SGC \text{ (ng/mL)}$ for digoxin $SGC \text{ (nmol/L)} \times 0.765 = SGC \text{ (ng/mL)}$ for digitoxin
Determination of the number of 40-mg vials needed ^a : $Q/0.5$
Empirical dosing recommendations with 40-mg vials (according to the authors)
Acute ingestion (adult): 2–4 up to 10–20 vials
Chronic ingestion (adult): 1–2 up to 3–6 vials

Note: For some authors, low dosage at least as starter should be sufficient; calculated full neutralizing doses of digoxin-Fab are expensive and may not be required

^aFab fragment dose (mg) = [molecular weight Fab (50 kd)/molecular weight digoxin (781 d)] \times body load (mg). Using this calculation, 0.5 mg of digoxin is neutralized by each 40-mg vial of Fab fragments

elimination phase and not during its distribution phase, which may last 6 h for digoxin [29]. Thus, since the lowest effective anti-digoxin Fab dose regimen is still not clearly determined, dosing regimens based on much lower initial doses were recently proposed, with 40 mg (one vial) for chronic poisoning and 80 mg (two vials) for acute poisoning, to be repeated after 60 min if inadequate response or recurrence, or earlier if there is a clinical deterioration [47]. Larger initial doses, including that which will achieve full neutralization, were recommended only in peri-arrest patients. Consistently, effectiveness of only 1–2 vials of anti-digoxin Fab fragments to bind all free digoxin in chronic digoxin poisonings was reported in a recent prospective observational study [16]. However, moderate improvement in

heart rate and potassium following the Fab administration was usually observed, suggesting that bradyarrhythmia and hyperkalemia in the chronically poisoned patients could be related to other comorbidities including chronic renal failure, heart diseases, and medications like β -adrenoceptor blockers and calcium antagonists.

On another hand, since equimolar neutralization with Fab fragments is expensive and sometimes not available in small hospitals, antidote administration is often delayed or withheld until serious arrhythmias occur. Under these conditions, ventricular fibrillation and asystole often result in postanoxic brain damage or refractory cardiogenic shock [11–17, 21]. Interestingly, factors associated with the use of anti-digoxin Fab fragments were identified based on a retrospective review of patient records over 2 years in 20 city hospitals in France [17]. Acute overdose (odds ratio, 15.74), antidote availability in the hospital (11.06), serum potassium (1.81), and heart rate (0.96) were significantly linked to the use of anti-digoxin Fab fragments. Mortality was clearly lower in Fab-treated (6%, 4/67) compared to untreated patients (15%, 117/770). Thus, considering their safety, prophylactic administration of anti-digoxin Fab fragments to prevent the occurrence of life-threatening arrhythmias was proposed [48]. In France, this approach was refined, taking into account (1) the prognosticators of acute digitoxin poisoning [20, 49], (2) the lack of evidence for the efficacy of pacing [33, 34], and (3) the frequency and severity of adverse effects of cardiac pacing. Two treatment strategies for two distinct situations of digitalis poisonings were proposed [50]. In patients exhibiting life-threatening disturbances, an equimolar neutralizing dose of anti-digoxin Fab fragments (curative dose) was recommended to be rapidly administered. In patients with mild bradycardia (<50 /min), regardless of the conduction disturbances, especially if associated poor prognostic factors [20], when atropine fails to accelerate the cardiac rhythm to greater than 50/min, a half equimolar neutralizing dose of anti-digoxin Fab fragments (“prophylactic” dose) was recommended. Particular attention was requested to >55 -year-old patients, patients with underlying cardiac disease,

and patients with serum potassium >4.5 mmol/L [51]. This French strategy based on the first-line use of anti-digoxin Fab fragments as curative vs. prophylactic treatment according to the patient’s conditions was associated with a reduced mortality rate (7.6%) [21].

There are no known contraindications, apart from allergy to sheep immunoglobulin. No interactions with other medications have been reported. During and after Fab administration, vital signs, ECG, and serum potassium levels should be recorded frequently to assess the efficacy and safety of treatment. Improvement in cardiac and noncardiac signs and symptoms of digitalis toxicity occurs rapidly after the anti-digoxin Fab fragments administration, with an initial response at a median of 19 min from termination of infusion and complete response at a median time of 88 min. [15] Neither age nor concurrent cardiac disease was associated with any significant delay in the initial response. Partial or no response resulted from (1) a moribund situation with multi-organ failure at the time of infusion, (2) an inadequate dose of Fab, (3) a concomitant toxicity from other drugs, and (4) an underestimated severity of underlying cardiac disease. None of the patients without heart disease who ingested a single acute digitalis dose did not respond to Fab [12]. The administration of additional doses of anti-digoxin Fab fragments should be considered in patients in whom life-threatening toxicity reappears or persists despite initial treatment. Recrudescence toxicity was reported in 20 of the 717 patients (2.8%) within 3 days of the initial Fab treatment in most of the patients, although as late as 4–11 days in a few patients [12]. Inadequacy of the initial dose was the only factor associated with recrudescence digitalis toxicity. In cases of massive digitoxin poisoning, recurrent toxicity has been reported 1–4 days after Fab administration and when the initial dose was less than the estimated adequate dose [35].

Measurement of serum digoxin concentrations after the administration of Fab fragments using the conventional analytical methods is no longer useful since measuring free plus bound digitalis. Detectable free digoxin concentrations may reappear

5–24 h or longer after Fab administration [53]. Measurement of the free digoxin concentration may be of value to determine the need for additional doses of Fab. When free serum digoxin concentration rebounds beyond 0.8 ng/mL (1.02 nmol/L), signs of digoxin intoxication recurred in some patients [53].

Safety is not an actual concern. Mild hypersensitivity reactions, including pruritic rash, facial swelling and flushing, urticaria, thrombocytopenia, shaking, and chills, rarely (~0.8%) occur. Hypokalemia may occur as elevated serum potassium concentrations decline rapidly, starting as soon as 1 h and completely normalizing within 4 h [15, 52]. Worsening of cardiac dysfunction after Fab fragment infusion is rare too (<3%) [15]. Data regarding the safety of Fab fragments in patients treated for more than one episode of digitalis toxicity are limited to draw any conclusion. Therapeutic redigitalization of the patient, if necessary, should be delayed until elimination of anti-digoxin Fab fragments is complete. Digoxin therapy can be administered safely 48–72 h after Fab infusion in patients with normal renal function [53].

Special Populations

Pediatric Patients

Digitalis poisoning has been reported in pediatric patients ranging from 1 day to 17 years old [35–39]. Iatrogenic intoxication is due to errors in the calculation or administration of the digitalizing and maintenance doses in smaller children. Accidental poisonings occur in young children and less commonly, adolescents may ingest digitalis in a suicidal attempt. Digitalis intoxication is most often accompanied by few clinical effects. Neurologic manifestations, life-threatening arrhythmias, conduction defects, and secondary hypotension may be observed like in adults. Hyperkalemia is uncommon. Anti-digoxin Fab fragments were consistently reported to be effective and safe in pediatric patients. Indications of antidote administration are based on the following recommendations: [39]

Known Digoxin Intoxication

- Strong evidence of acute ingestion of ≥ 0.1 mg/kg digoxin
- Elevated (steady-state) serum digoxin concentration ≥ 5 ng/mL (6.4 nmol/L)

Signs and Symptoms of Digitalis Toxicity

- Rapidly progressing features of digoxin toxicity
- Potentially life-threatening arrhythmias, including cardiac conduction disturbances
- Severe hyperkalemia (≥ 6.0 mmol/L)

The prophylactic administration of anti-digoxin Fab fragments was also considered in children, the main objective being, however, to avoid any delay in their administration. Dosage is similar to adults, paying attention to the dilution to avoid fluid overload in small children. The empirical Fab dosing is 400–800 mg in acute poisoning and 40–80 mg in chronic toxicity. Increased serum potassium concentration usually normalizes within 4 h of administration [36]. In the main study, no cases of hypersensitivity have been reported, while hypokalemia occurred in one case and recurrence of cardiac conduction defects after treatment in three children requiring a repeated dose to reverse [39].

Pregnant Patients

During pregnancy, digitalis overdose may result in maternal and fetal digitalis poisoning. Pregnant patients with acute digitalis overdose should be treated similarly to nonpregnant patients. However, there are no definitive data regarding the efficacy or safety of anti-digoxin Fab fragments in pregnant women.

Elderly Patients

Digoxin toxicity in the elderly is common, ranging from minor gastrointestinal symptoms to life-threatening dysrhythmias. Increased risk of toxicity in the

elderly is related to their multiple medications, their decreased renal clearance, and the increased risk of unintentional ingestion of repeated doses due to their cognitive impairments. Mild-to-moderate digoxin toxicity in the elderly may be difficult to recognize from other “signs of old age,” i.e., somnolence, decreased hearing, confusion, agitation, poor appetite, nausea, vomiting, and diarrhea [54]. In the treated elderly patients, chronic toxicity should be suspected in the new onset of dysrhythmias, malaise, gastrointestinal disturbances, or mental status changes. Lethargy, depression, and confusion seem to occur almost exclusively in the elderly [55]. Advanced age seems to be an independent poor prognostic factor.

Renal Dysfunction Patients

Patients with renal dysfunction are at high risk of digoxin poisoning. Fab therapy is effective in patients with renal dysfunction [11–17]. Fab fragments should be given to patients with renal impairment at the same dose as for patients with normal renal function [56]; however, elimination of digoxin-specific Fab complexes is prolonged. Total body clearance of Fab fragments is related linearly to creatinine clearance, whereas their apparent volume of distribution is not affected [56]. Free digoxin concentrations decrease rapidly after Fab therapy but rebound at about 77 ± 46 h postinjection [57]. The magnitude by which free digoxin concentration rebounds is unaffected by the degree of renal dysfunction. There is no evidence to support a dissociation of the Fab/digoxin complexes over extended periods [53]. Because there are rarely complications resulting from circulating Fab/digoxin complexes for a prolonged period, however, there is little evidence to recommend any extrarenal technique to enhance their elimination [27]. Monitoring free serum digoxin concentrations may be of value in selected patients to guide additional Fab dosing, confirm possible rebound toxicity, or guide the re-initiation of digoxin therapy [57].

Key Points in Digitalis Poisoning

1. To date, digoxin poisoning mainly results from chronic toxicity in long-term treated elderly patients with underlying cardiac diseases due to acute renal onset or drug-drug interactions rather than from the suicidal or accidental exposure to a single high digoxin dose.
2. Digitalis poisoning may be life-threatening with the sudden onset of fatal ventricular dysrhythmias.
3. Mild-to-moderate digoxin toxicity in the elderly may be difficult to recognize from other “signs of old age.”
4. The emergency determination of the serum digitalis concentration is mandatory in each patient with suspected digitalis toxicity.
5. Prognosticators including age >55 years, serum potassium >4.5 mmol/L, and atrio-ventricular block of any degree should be recognized on patient management.
6. Antidysrhythmic drugs and cardiac pacing should be not be used anymore if anti-digoxin Fab fragments are available.
7. Anti-digoxin Fab fragments represent the first-line antidote in the presence of hyperkalemia, cardiac conduction disturbances, or life-threatening arrhythmias.
8. The currently recommended dosing regimen of anti-digoxin Fab fragments is to administer 40 mg (one vial) for chronic poisoning and 80 mg (two vials) for acute poisoning and repeat after 60 min if inadequate response or recurrence or earlier if clinical deterioration.
9. Prophylactic semi-molar dosing of anti-digoxin Fab fragments in the presence of bad prognosticators has been proposed with success to reduce digitalis-related fatality.
10. The extracorporeal removal techniques are unlikely to improve the outcome of digoxin-toxic patients whether or not anti-digoxin Fab fragments is administered.

Acknowledgments The author would like to thank Prof. Frédéric Lapostolle who contributed to the first version of this chapter.

Antidysrhythmics achieve their therapeutic goals of rhythm control through blockade or antagonism of various cardiac channels or receptors. In the Vaughan Williams convention [1], which endures despite its limitations due to its simplicity and clinical applicability, class I antidysrhythmic agents block the cardiac sodium channel by intent. As highlighted by the Cardiac Arrhythmia Suppression Trials (CAST I and II) of encainide, flecainide, and the subsequently withdrawn moracizine, these agents have the potential to increase mortality even at therapeutic dosing [2]. Cardiac sodium channel blockade may be an “on target” effect of class I agents or antidysrhythmics from other Vaughan Williams classes or an “off target” effect of a host of agents from multiple pharmaceutical classes, including antibiotics, antiepileptic drugs; cyclic, selective serotonin reuptake inhibitor, and serotonin–norepinephrine reuptake inhibitor antidepressants; antihistamines; antipsychotics; amide and ester local anesthetics; mood stabilizers; and opioids (Tables 1 and 2). Of note, this sodium channel blockade may be identified by other terminology, e.g., the “membrane-stabilizing effects” of certain beta-adrenergic antagonists or eponymous “local anesthetic effects.”

This is an update of the chapter written by Paul Kolecki in the first edition of this text.

Table 1 Selected agents with sodium channel antagonism

Drug classification	Drug subclassification	Example(s)
Antibiotics	Antimalarials	Chloroquine Hydroxychloroquine Quinine
Antidysrhythmics	Vaughan-Williams Class IA Vaughan-Williams Class IB Vaughan-Williams Class IC	Quinidine Lidocaine Propafenone
	Vaughan-Williams Class II (Beta-adrenergic antagonists)	Acebutolol Betaxolol Carvedilol Labetalol Metoprolol Oxprenolol Pindolol Propranolol
	Vaughan-Williams Class III (Potassium channel blockers)	Amiodarone Dronedarone
	Vaughan-Williams Class IV (Calcium channel antagonists)	Diltiazem Verapamil
Anti-epileptics	Hydantoins	Phenytoin
	Iminostilbenes	Carbamazepine
	Phenyltriazines	Lamotrigine
Antidepressants	Cyclic antidepressants	Amitriptyline Desipramine
	Selective serotonin reuptake inhibitors	Citalopram Escitalopram Fluoxetine Fluvoxamine
	Serotonin–norepinephrine reuptake inhibitors	Venlafaxine
Antihistamines	First-generation H ₁ antagonists	Dimenhydrinate Diphenhydramine Orphenadrine
	Second-generation H ₁ antagonists	Terfenadine
Antipsychotics	Dibenzoxazepines	Loxapine
	Phenothiazines	Chlorpromazine Fluphenazine Mesoridazine Thioridazine
Local anesthetics	Amide local anesthetics	Bupivacaine Lidocaine Ropivacaine
	Ester local anesthetics	Cocaine Procaine
Mood Stabilizers	Minerals	Lithium salts
Opioids	Semisynthetic opioids	Buprenorphine
	Synthetic opioids	Methadone Propoxyphene Tramadol

Table 2 Pharmacokinetics of antidysrhythmic pharmaceuticals with sodium channel antagonism [1, 3, 8–12]

Drug classification	Drug name	Volume of distribution (L/kg)	Elimination half-life (hours)	Relevant active metabolite(s)	Log P	Log D (at pH 7.0)
Vaughan-Williams Class IA (Sodium channel blockers)	Disopyramide ^{a, b}	0.6–1.5	4–10		2.86	0.07
	Procainamide ^{a, c}	3.3–4.8	3–4	Yes	1.23	–1.43
	Quinidine ^{a, b}	1.8–3.0	4–10	Yes	–1.55	1.35
Vaughan-Williams Class IB (Sodium channel blockers)	Lidocaine	1.3	1.5–2	Yes	2.36	0.83
	Mexiletine	6–12	9–15		2.16	0.58
	Tocainide	1.4	12–15		0.76	–0.37
Vaughan-Williams Class IC (Sodium channel blockers)	Encainide	2.7–4.3	2.3–11		4.63	2.39
	Flecainide	9–10	10–18		3.47	0.55
	Propafenone ^d	2.5–4.0	2–32	Yes	4.63	2.39
Vaughan-Williams Class II (Beta-adrenergic antagonists)	Acebutolol	1.0	3–4		2.59	0.52
	Betaxolol	7.7–8.8	15		2.69	0.56
	Carvedilol ^e	1.5	7–10		4.23	3.16
	Labetalol ^e	3.4–10.7	3–4		2.87	0.99
	Metoprolol	5.6	3–4	Yes	1.79	–0.34
	Oxprenolol	1.3	1–2		2.10	–0.10
	Pindolol	1.2–2.0	2–5		1.97	–0.19
	Propranolol	3.3–5.5	3–5		3.10	0.99
Vaughan-Williams Class III (Potassium channel blockers)	Amiodarone ^f	~60	58 days	Yes	8.59	6.29
	Dronedarone ^{e, f}	1200–1400L	24	Yes	7.35	N.A.
Vaughan-Williams Class IV (Calcium channel blockers)	Diltiazem	4.6–5.3	4		4.53	2.64
	Verapamil ^b	3.4	3–7	Yes	4.91	2.91

N.A. not available

^aAdditional antimuscarinic activity

^bAdditional class III activity

^cAdditional class III activity through *N*-acetylprocainamide metabolite (acecainide)

^dAdditional beta-adrenergic antagonism and L-type calcium channel blockade

^eAdditional alpha-adrenergic antagonism

^fAdditional class I, II, and III activity

Clinical Pharmacology

The absorption of antidysrhythmics is nearly complete after oral administration; however, their bioavailability may be reduced by first-pass hepatic metabolism. Protein binding in excess of 80% can occur with amiodarone, dronedarone, encainide, lidocaine, propafenone, propranolol, quinidine, and verapamil [3]. In overdose, toxicokinetics may be modified by drugs or coingestants with opioid or anticholinergic properties that decrease peristalsis or

particularly large ingestions, which independently decrease intestinal motility [4, 5]. Antidysrhythmics' relatively large volumes of distribution (V_D) can be altered in comorbidities. For example, quinidine's V_D can vary from 0.5 L/kg in congestive heart failure (CHF) to 2–3 L/kg in healthy adults to 3–5 L/kg in cirrhosis [6]. Terminal half-lives vary according to the specific agent and comorbid conditions, particularly CHF, and may be further prolonged in overdose [7].

The *SCN5A* gene encodes the tetrodotoxin-resistant, $Na_v1.5$ voltage-gated cardiac sodium

Fig. 1 Activation and inactivation of the Na^+ current linked to the channel conformation. Schematic Na^+ current (bottom) recorded during a voltage pulse (middle). Activation of the current corresponds to an increasing number of Na^+ channels in the open conformation (top) due to the depolarization; inactivation corresponds to an increasing number of channels passed from the open to the inactivated conformation. Repolarization allows the inactivated channels to restore the closed conformation. (From Baró I, Escande D. *Basic Physiology of Ion Channel Function*. In: Gussak I, Antzelevitch C, Wilde AAM, et al., eds. *Electrical Diseases of the Heart: Genetics, Mechanisms, Treatment, Prevention*. London: Springer London, 2008:11–23.)

channel alpha subunit, the desired target of the Vaughan Williams class I agents. $\text{Na}_v1.5$ cycles between resting (closed), activated (open), and inactivated (closed) states (Fig. 1). Closed states are impermeable to sodium. $\text{Na}_v1.5$ contains four homologous transmembrane domains (D1–D4), each consisting of six transmembrane spanning sections (S1–S6) (Fig. 2) [13]. The central pore permitting sodium ion transit is formed by the four S5–S6 sections and their intervening loop domains. A “P-loop,” connecting S5 and S6, folds back into the membrane, and the tips of the four P-loops come together to form the narrow ion selectivity filter determined by a ring of amino acids (asparagine, glutamate, lysine, and alanine) [14]. The receptor site for sodium channel blockers is a collection of amino acid residues that line the

inner surface of the S6 segments of D1, D3, and D4 to create a three-dimensional drug receptor site whose occupancy blocks the pore (Fig. 3) [15].

Beta-subunits and other regulatory partners are important interacting proteins [16]. Congenital $\text{Na}_v1.5$ loss of function mutations is associated with the Brugada syndrome, which places the individual at risk for sudden cardiac death from ventricular dysrhythmia [16]. Class IA and IC sodium channel blockers, such as ajmaline and flecainide, are used to elicit characteristic ST-segment elevations and unmask occult Brugada disease (Fig. 4) [17, 18].

Class I agents may have additional receptor targets. For example, disopyramide, quinidine, and procainamide have antimuscarinic and Class 3 activity, even in therapeutic dosing [19]. Conversely, certain class II–IV agents possess class I effects and other complex properties (Table 2). Some class I agents have active metabolites which exert significant effects. Lidocaine’s metabolite, monoethylglycylxylidide, although less potent, is active and has a longer half-life than lidocaine. Procainamide’s metabolite, *N*-acetylprocainamide (acecainide), is a class III antiarrhythmic agent. Comorbidities or drug-drug interactions may affect metabolite formation [7].

Pathophysiology of Cardiac Action Potentials and Myocardial Toxicity Resulting from Sodium Channel-Blocking Antidysrhythmic Poisoning

In nonpacemaker cells, the action potential consists of five phases (Fig. 5). Phase 4 refers to the resting state, during which voltage-gated sodium channels are closed until activated in response to the spread of electrical membrane depolarization from adjacent tissue or the opening of nearby ligand-gated excitatory ion channels. As the membrane depolarizes and a certain threshold is reached, channels become activated within 1 ms through a simultaneous outward movement of all four S4 segments, resulting in

Fig. 2 Structure and interactions of the voltage-gated sodium channel α subunit with β subunit, and the fibroblast growth factor homologous factor (FHF). Nav α represents the α subunit of the sodium channel $\text{Na}_V1.5$. $\text{Na}_V1.5$ consists of four pseudo-homologous domains (DI through DIV), each bearing six transmembrane helical segments (S1 through S6) and partial reentrant loops between S5 and S6 that form the sodium ion selectivity filter (“P loop”). The S4 segments have periodic cationic residues that constitute the voltage sensors. The S6 segments provide the inner walls of the channel beneath the ion selectivity filter. The channel has cytoplasmic amino (N) and carboxyl (C) tails, and the four domains are connected by cytoplasmic loops (not to scale). The small loop between DIII and DIV includes a short α -helical region and the IFM triad required for fast channel inactivation. The C-tail critically modulates fast inactivation and is the site for physical interactions with channel β

subunits and FHFs (arrows). Nav β Beta-subunits (Nav2.1–Nav2.4) are single-pass transmembrane proteins with an extracellular immunoglobulin-like domain and a short cytoplasmic tail that mediates binding to Nav α . Nav β 4 bears a unique motif in its C-tail that serves as a channel-blocking particle responsible for resurgent current. FHFs (FHF1–FHF4, each with multiple isoforms bearing different N-termini) are small cytoplasmic proteins that assume a β -trefoil fold bearing the surface for interaction with the Nav α C-tail. The A-type isoforms of FHFs have N-terminal motifs that serve as long-term inactivation particles. Nav β 4 and A-type FHF particles terminate transient sodium current by competing with the Nav α fast inactivation machinery. (From Goldfarb M. *Voltage-gated sodium channel-associated proteins and alternative mechanisms of inactivation and block*. *Cell Mol Life Sci*. 2012;69(7):1067–76.)

the opening of the channel pore and, due to the electrochemical gradient, inward conductance of sodium ions [16]. This produces the maximum upstroke velocity during phase 0 (V_{max}), which approximates the magnitude of sodium ion influx through opened sodium channels [3, 20]. This conduction results in the normally narrow QRS interval reflected on the surface electrocardiogram. Once depolarized, sodium channels are rapidly closed as the intracellular loop between D3 and D4 acts as a “lid” to close the channel pore [16]. Physiological conditions permit inactivated channels to remain in a closed state until the cell membrane is repolarized, permitting recovery from inactivation to a resting state (Fig. 1). Phase 1 of the nonpacemaker cell action potential begins with this inactivation of

sodium channels at the peak of the action potential and is marked by a brief period of rapid electrical repolarization. Phase 2, the plateau phase, results from a balance between calcium influx through voltage-gated calcium channels and potassium efflux. There is a relatively smaller and more gradual change in the membrane potential during phase 2 because the net ion conductance is minimal. Rapid repolarization (phase 3) results from further activation of transmembrane potassium channels and outward movement of potassium. The cell membrane and its sodium channels then return to the resting state (e.g., phase 4) and again are ready for depolarization and activation. During the action potential, a very small fraction of sodium channels does not inactivate completely and

Fig. 5 Currents and channels involved during a typical cardiac action potential. The various phases are indicated by numbers (0–4). The approximate relative time courses of the currents associated with the channels encoding the principal channel subunits are shown symbolically, without representing their magnitudes relative to each other. I_{Na} , inward excitatory current carried by sodium ions; I_{Ca-L} , L-type calcium channels current; I_{Ca-T} , T-type calcium

channels current; $I_{Na/Ca}$, current generated by the Na/Ca countertransport system; I_{K1} , inward rectifier potassium current; I_K , delayed rectifier potassium current; I_{TO} , transient outward potassium current; I_{KACh} , acetylcholine-sensitive potassium current; I_{KATP} , ATP-sensitive potassium current. (From Langan MN. The impact of recent ion channel science on the development and use of antiarrhythmic drugs. *Curr Cardiol Rep*. 1999;1(4):302–7.)

contributes a “sustained current” or “late current” to the action potential duration [3].

The action potential of pacemaker cells is composed of only three phases. In phase 4, which is relatively slow, the hyperpolarization-activated pacemaker current is a mixed Na-K inward current, mediated by cAMP under beta-adrenergic (positive) and muscarinic (negative) control [21]. Additional time- and voltage-dependent ionic pacemaker currents have been identified. A sodium-calcium exchanger current (I_{NCX}) has also been identified. Low voltage-activated T-type calcium current triggers local release of

calcium from the sarcoplasmic reticulum, which in turn stimulates I_{NCX} to depolarize the pacemaker potential to threshold [22]. When the threshold potential is reached, phase 0 is initiated, and influx of calcium occurs to activate the cardiac ryanodine receptor. In contrast to nonpacemaker tissue, little sodium influx occurs during phase 0. Phase 3 repolarization, as in nonpacemaker cells, is due almost entirely to potassium efflux. The summation of pacemaker and other electrical currents across the cardiac cycle and the representation on the surface ECG is shown in Fig. 6.

Sodium channel-blocking antidysrhythmics can produce major adverse cardiotoxic effects including intraventricular conduction defects, hypotension, and supraventricular or ventricular dysrhythmias. Intraventricular conduction defects occur as a result of a sodium channel blockade-related reduction in the slope of phase 0 of the nonpacemaker cell action potential. Class IA, Class IC, and similarly acting drugs such as cyclic antidepressants (CAs) impair V_{max} (Table 3) [3, 20]. Clinical manifestation of this includes widening of the QRS complex and/or the development of bundle-branch block-like

morphology. In a broad molecular assay study of 132 class I antidysrhythmics and other QRS prolonging drugs, QRS prolongation occurred on average at free plasma levels 15-fold below their median blocking potency (IC_{50}) at human cardiac Nav1.5 channels [23].

Toxic exposure to sodium channel-blocking antidysrhythmics may also induce ventricular monomorphic tachycardia or fibrillation. These potentially lethal dysrhythmias are thought to occur by slowing intraventricular conduction to the point that unidirectional block and reentrant

Table 3 Differences among class I antiarrhythmic drugs [2, 19, 26, 27]

Drug classification	Phase 0 depression	Repolarization	Action potential duration
IA	Moderate	Prolonged	Prolonged
IB	Minimal	Shortened	No change or shortening
IC	Significant	Minimal or no effect	Minimal effect

circuits develop [24]. These reentrant circuits can further degenerate into ventricular tachycardia and fibrillation [25].

Access to the sodium channel blocker receptor site by large or hydrophilic drugs (Fig. 3) requires opening (of the usually closed) intracellular activation gate. Sodium channels' "use-dependent block" – also known as "rate dependent block" – thus logically proceeds from more facile binding when the channel is frequently opened (e.g., at faster heart rates). Fenestrations leading from the lipid phase of the membrane sideways into the drug receptor site provide a separate, specific hydrophobic access pathway for binding of small hydrophobic drugs during the channel's resting state [15]. In contrast to IA and IC agents, lidocaine and class IB antidysrhythmics block sodium channels predominantly in their inactivated state at the end of depolarization, during early repolarization, and during periods of myocardial ischemia, and thus have minimal effects on phase 0 depolarization and do not prolong action potential duration [26]. Pharmacogenetic interactions provide further opportunity for different binding and gating effects. For example, SCN5A promoter haplotype variants demonstrate altered flecainide efficacy and toxicity in the form of PR prolongation and QRS widening [28].

As was established from congenital Brugada syndrome loss of function mutants, sodium toxic channelopathy creates the potential for sudden ventricular dysrhythmia in susceptible patients. Class III effects of many of the class IA agents may result in impaired repolarization from potassium channel blockade. Both transmural and epicardial dispersion of repolarization may occur, lengthening the QT interval and predisposing the involved myocardium to the occurrences of polymorphic ventricular tachycardia.

Hypotension after sodium channel-blocking antidysrhythmic poisoning likely results from impaired myocardial contractility, as influx of sodium and calcium is coupled to the release of intracellular calcium stores. Hypotension may also occur secondary to reduced vascular smooth muscle contractility and resultant vasodilation. The peripheral alpha-adrenergic antagonist actions of selected sodium channel-blocking antidysrhythmics (e.g., quinidine, CAs) may also contribute substantially to this clinical effect.

Many sodium channel-blocking antidysrhythmic agents (e.g., type IA agents) possess antimuscarinic properties, resulting in sinus tachycardia after overdose [1, 19]. However, large overdoses of these antidysrhythmics may depress pacemaker cell automaticity, causing sinus bradycardia, junctional escape or other ventricular arrhythmias, and asystole. In sodium channel blocker poisoning by anticholinergic antidysrhythmics, the combination of a wide QRS complex and bradycardia is ominous, as it suggests that the sodium channel blockade is so profound that the myocardium is unable to mount a tachycardic response to muscarinic antagonism.

The mechanism of decreased automaticity in pacemaker cells during severe sodium channel blockade is not entirely clear in class I agents lacking beta-adrenergic antagonism. In the spontaneously beating sinus venosus of the frog, bupivacaine-induced reversible negative chronotropy, a decreased diastolic depolarization rate, and a prolongation of sinus cycle length [29]. While atropine attenuated bupivacaine's effect on spontaneous rate of firing, V_{max} and action potential amplitude worsened. An analogous situation has been studied in Purkinje fibers, in which high doses of imipramine, an anticholinergic sodium channel-blocking CA, depressed the slope of phase four of the pacemaker action potential to asystole [30].

Clinical Presentation and Life-Threatening Complications

Assuming there is no change in gastrointestinal (GI) motility, transit, or absorption, asymptomatic patients ingesting antidysrhythmics are unlikely to

develop further symptoms if the time since ingestion is greater than 6 h for immediate-release products and 24 h for sustained-release formulations [31]. The adverse clinical effects of antidysrhythmics seen in therapeutic use – hypotension, dysrhythmias, conduction disturbances, paradoxical prodysrhythmic response [19, 26, 32] – are magnified in overdose. In a series of 120 class IC antidysrhythmic overdoses, mean mortality was 22.5% [33]. Nausea was the typical, earliest symptom. Heart rate may depend on the associated on- or off-target drug effects. For example, the antimuscarinic properties of disopyramide, procainamide, quinidine, CAs, and diphenhydramine or sympathomimetic properties of cocaine may produce tachycardia, while bradycardia predominates with propafenone and membrane stabilizing beta-adrenergic receptor antagonists. Hypotension, junctional escape, myocardial depression, and asystole have been observed. Conduction defects may include prolonged QRS, high-grade atrioventricular nodal blocks, and bundle-branch blocks, as well as ventricular dysrhythmias (e.g., ventricular tachycardia and ventricular fibrillation). “Quinidine syncope” was identified decades ago as an additional therapeutic complication [34]. Agents or metabolites with class III effects (Table 2) further risk QT interval prolongation and *torsades de pointes*. Class I antiarrhythmic agents may elicit Brugada patterns, amplifying existing sodium ion channel defects with a potency inversely proportional to the rate of dissociation of the drug from the sodium channel [17, 18, 35].

Central nervous system effects, including seizures, may portend subsequent cardiovascular collapse in lidocaine poisoning. The class IA antimuscarinic antidysrhythmics may manifest seizures as well as an anticholinergic syndrome characterized by agitation, coma, respiratory depression, urinary retention, tachycardia, anhidrosis, and depressed GI motility [19]. Seizures may accompany other sodium channel antagonists (e.g., cocaine, CAs, citalopram, diphenhydramine, propoxyphene, etc.).

Hypoglycemia has been reported with quinidine and disopyramide and is also a concern with class II agents [19]. Procainamide is associated

with hypersensitivity reactions including fever, rash, and agranulocytosis [19].

Diagnosis

The differential diagnosis includes a myriad of substances and environmental toxins capable of exerting primary or secondary adverse cardiovascular effects. Pharmaceuticals of note that produce hypotension and/or bradycardia include the class I-IV antidysrhythmics, cardiac glycosides (digoxin), imidazoline derivatives (clonidine, oxymetazoline, tetrahydrozoline, etc.), nitrates, and renin–angiotensin system antagonists. Depending upon the degree of exposure, other agents in the classes listed in Table 1, sedative-hypnotics, mitochondrial toxins, and others may cause cardiovascular compromise. A detailed history and clinical evaluation can support the diagnosis of sodium channel-blocking antidysrhythmic poisoning.

The importance of the ECG in evaluating antidysrhythmics’ toxic effects has been recognized for decades [36]. Disturbances in rate and atrioventricular conduction are readily assessable. Prolongation of the QRS interval beyond 100 milliseconds is a hallmark of impaired myocardial conduction and intraventricular conduction delay seen in sodium channel blocker antidysrhythmic poisoning. QRS widening predicts seizures and ventricular dysrhythmias in CA poisoning [37, 38]. Abnormal right ventricular depolarization, leading to terminal rightward depolarization of the last 40 milliseconds of the QRS complex, gives rise to a terminal R wave in lead AVR and/or an S wave in leads I and AVL [38, 39]. While these additional findings provide reliable ECG criterion for CA toxicity, their predictive value for other sodium channel-blocking antidysrhythmic is less established. The QT interval should be evaluated for delayed repolarization [19]. Tachycardia from antimuscarinic side effects accompanying a wide QRS complex from sodium channel blockade may produce a rhythm that has been mistaken for ventricular tachycardia [40].

While QRS widening is typical of sodium channel blockers, toxicity from sodium channel

openers (e.g., aconitine, amantadine, grayanotoxin, veratridine, etc.) may manifest as QRS widening. QRS widening may be also mimicked by additional pharmaceuticals such as bupropion (though alternative mechanisms such as inhibition of intercellular gap junctional communication) and colchicine (a microtubule inhibitor causing myocyte injury and altered calcium handling) [41, 42]. As might be anticipated from a toxic channelopathy superimposed upon occult mutation, the Brugada pattern has been reported in cases of class I agent therapy and toxicity, as well as in poisonings by noncardiac agents, such as CAs and cocaine [35, 43–45].

A focused emergency ultrasound (FOCUS) may rapidly assess several critical physiological questions in overdose (level III recommendation) [46, 47]. Cardiac imaging provides a gross assessment of the degree to which left (and right) ventricular contractility is preserved or compromised; pulmonary vascular congestion may be evident from pulmonary sonographic B-lines; and inferior vena cava size and collapsibility can provide a noninvasive estimation of right-sided filling pressures.

As significant hypoglycemia may accompany class IA agents, frequent blood glucose monitoring is advisable [19]. Specific antidysrhythmic drug concentrations, even if available, are not typically returned in a timescale to aid clinical management. Class V agents such as digoxin and magnesium are an exception. Coingestants such as acetaminophen, salicylates, ethanol should also be considered for exclusion. Acid–base status should be obtained frequently to detect acidemia and to guide alkalization therapy.

Treatment

A definitive airway, as needed, should ensure adequate oxygenation and ventilation, so as to preclude absolute or relative respiratory acidosis. Continuous cardiopulmonary monitoring and sufficient peripheral or central vascular access to permit resuscitation with intravenous fluids, chronotropes, inotropes, and other therapies to sustain cardiovascular function and end organ perfusion should be ensured.

Decontamination

Given the potential for severe morbidity and mortality with antidysrhythmic poisoning, GI decontamination should be considered in every patient with oral exposure (Grade III recommendation) [33]. The nuances of this decision-making are beyond the scope of this chapter. Approaches to GI decontamination have generally not been shown to alter the outcome or the clinical course in patients. However, a careful risk-benefit assessment – taking into account the exposure, amount, and its timing; the patient's current and anticipated condition; comorbidities and coingestants; and provider skill – should guide the decision to employ adjuncts to alter toxicokinetics. Depending on the agent(s), these may include upper GI tract removal through orogastric lavage, intraluminal binding with activated charcoal, or increasing intestinal transit time and rectal expulsion effected through whole-bowel irrigation. The most recent American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists position paper advised that “gastric lavage should not be performed routinely,” while allowing for “rare” situations of use (Grade III recommendation) [48]. However, several key points are relevant. While GI decontamination measures should be performed early, overdose, in and unto itself, delays gastric emptying (Level II-1 evidence) [5]. Drugs or coingestants with opioid or anticholinergic properties (e.g., CAs) decrease peristalsis (Level II-1 evidence) [5, 49]. These properties render agents more amenable to GI decontamination, such as with activated charcoal (Level II-1 evidence) [4]. New evidence suggests that not infrequently, GI intraluminal pills or pill breakdown products can be found in decedents and even in the stomach of those who survive to the ICU (Level III evidence) [50]. Thus, decontamination may be particularly important in cases of significant gut burden, ongoing absorption, modified- or sustained-release preparations, or drugs or coingestants known to slow GI transit such as those with antimuscarinic or opioid properties [50]. While human studies attempting to

demonstrate a survival benefit of any decontamination modality remain inconclusive, most excluded sick patients or those most likely to benefit, or included patients likely to benefit from supportive care alone [51–53]. Some studies including significantly compromised patients have found benefit to gastric emptying in this subset (Level II-2 evidence) [54]. Particularly deadly toxins with little or absent specific antidotal options have also benefitted from early gastric emptying [55]. In a meta-analysis of healthy volunteers, activated charcoal reduced drug exposure in a sigmoid dose-dependent fashion for up to 4 h after exposure (Level I evidence) [56]. WBI can be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs in situations when activated charcoal is less effective (Grade III recommendation) [57]. Attention to airway protection, contraindications, and the not insignificant complications of the various GI decontamination methodologies is paramount.

Hypertonic Sodium Bicarbonate

The recognition of quinidine-induced ECG alterations in the early 1950s [36] pointed to therapy with molar sodium lactate – which is rapidly hepatically metabolized to sodium bicarbonate – in initial case reports and subsequent human studies of quinidine and procainamide poisoning [58, 59]. Hypertonic sodium bicarbonate is the initial treatment of choice for intraventricular conduction defects, ventricular dysrhythmias, and the negative inotropic effects of a sodium channel-blocking antidysrhythmic overdose. By the 1970s, administration of hypertonic sodium bicarbonate in cases of massive CA ingestion (greater than 2.5 g) decreased mortality from 15% to less than 3% [60]. In CA patients requiring intensive care, sodium bicarbonate therapy improved blood pressure in 96%, narrowed the QRS in 80%, and improved consciousness in patients with altered mental status in 47% [61]. Successful treatment with sodium bicarbonate has been reported in patients poisoned with many other sodium channel-blocking antidysrhythmics, including

encainide, flecainide, and propafenone, as well as other sodium channel blockers [40, 62–64].

Early work that suggested sodium bicarbonate mediated altered CA plasma protein binding to alpha-1-acid glycoprotein (AAG) was not borne out by subsequent experiments with exogenous AAG administration or experiments in isolated Purkinje fibers absent protein [20, 65]. Both sodium concentration and change in blood pH appear to play a role in improving hemodynamic and ECG parameters. The increase in extracellular pH and sodium concentration by sodium bicarbonate administration independently and additively improved Vmax and action potential amplitude in canine models of amitriptyline-induced cardiotoxicity [20]. Similarly, both increased sodium concentration and alkalinization significantly reduced the depressant effects of flecainide and mexiletine on Vmax, although the adverse effects of disopyramide were not mitigated [66]. Increasing the extracellular sodium concentration shifted the flecainide dose–response curve, apparently by decreasing flecainide binding affinity [67]. While amitriptyline-induced ventricular tachydysrhythmias in dogs demonstrated a greater response to the administration of sodium bicarbonate than to hypertonic sodium chloride, the reverse was seen in nortriptyline-poisoned swine [68, 69]. Addition of sodium bicarbonate to achieve a pH of 7.52 mitigated cocaine-induced QRS widening in guinea pig hearts [70].

Respiratory Alkalosis to Induce Serum Alkalization

Both sodium supplementation and serum alkalization are important components in the treatment of sodium channel blockade with ECG manifestations. Theoretically, alkalization can be achieved through repetitive boluses followed by continuous infusion of sodium bicarbonate or by inducing respiratory alkalosis. Hyperventilation can be accomplished when patients succumb to the anticipated or actual need for mechanical ventilation. Canine studies supported equivalent suppression of amitriptyline-induced ventricular

ectopy with hyperventilation to a pH similar to that produced by sodium bicarbonate (7.48); however, sodium bicarbonate outperformed hyperventilation in CA-poisoned rats and swine [68, 69, 71]. Hyperventilation-induced alkalization has narrowed the QRS in human cases (Level III evidence) [72]. While hyperventilation also mitigates severe hypernatremia and fluid overload from sodium bicarbonate, no clinical trial has compared the primary administration of sodium bicarbonate with induced alkalization and saline. If a hyperventilation strategy is chosen, sodium bicarbonate boluses should be administered until adequate serum alkalization to a pH of 7.45–7.55 is achieved and acid–base status closely monitored.

Hypertonic Saline

Hypertonic (3–7.5%) saline has been utilized in cases of CA poisoning-induced ventricular arrhythmias, QRS widening, and hypotension refractory to hypertonic sodium bicarbonate therapy [73, 74]. Optimal human dose of hypertonic saline remains undetermined, and careful attention is necessary to prevent severe hypernatremia. Current data do not conclusively demonstrate the superiority of hypertonic saline over sodium bicarbonate for the treatment of sodium channel-blocking antidysrhythmic toxicity [69, 75]. In addition, the safety and efficacy of the use of hypertonic solution in the treatment of poisoning have not been demonstrated in controlled clinical studies. Pulmonary edema may occur if hypertonic solutions are used and cardiac output is depressed. Hypertonic saline may not reverse sodium channel blockade seen in lidocaine poisoning [76].

Intraventricular Conduction Delays

Based primarily on the experience with CAs, the majority opinion of poison center medical directors was to administer sodium bicarbonate boluses when the duration of the QRS complex reached or exceeded 100 milliseconds, although many used a cut-off of 120 milliseconds (Grade III evidence) [77, 78]. Other patient-specific factors such as

comorbidities, coingestants, hypotension, seizures may inform decision-making. A typical initial dose of hypertonic sodium bicarbonate is 1–2 mEq/kg by rapid intravenous infusion, preferably with continuous ECG monitoring of the QRS complex (Level III recommendation) [77].

As institutions usually stock either an 8.4% solution (1 mEq/mL sodium and bicarbonate ions) or a 7.5% solution (0.892 mEq/mL sodium and bicarbonate ions), a single “standard” 50-mL ampule of 8.4% or 7.5% solution would deliver 50 or 44.6 mEq of NaHCO_3 , respectively. Multiple, frequent boluses may be required, either as initial therapy or as the bolus effect dissipates due to redistribution, with return of QRS widening [79]. Severe toxicity, as manifested by persistent QRS widening or unstable ventricular dysrhythmias, may necessitate massive interval NaHCO_3 bolus dosing [80]. Due to the transient effect of bolus dosing, a continuous infusion of “normal” bicarbonate infused at double the standard rate of intravenous fluid maintenance is typically also provided. This “normal” bicarbonate solution is prepared by adding three ampules of sodium bicarbonate (totaling 132–150 mEq) in 1 L 5% dextrose solution in water (D5W). Typically, the rate and bolus dosing are titrated so as not to exceed a serum pH of 7.55, although some authorities recommend a ceiling pH of 7.60, balancing QRS width and clinical status with the potential side effects of hypernatremia, volume overload, hypokalemia, and hypocalcemia (Level II-2 and Level III recommendation) [61, 77].

Dysrhythmia

Sinus tachycardia accompanying sodium channel antidysrhythmic poisoning usually results from antimuscarinic effects. While this might be a concern from the perspective of rate-dependent block, treatment narrowly focused on this sign can be misguided. Physostigmine, a short-acting anticholinesterase, has been reported to both slow the heart rate and subsequently narrow the QRS complex in patients poisoned with sodium channel blockers (albeit complicated by physostigmine-associated general tonic-clonic seizures) [81]. While slowing

the heart rate might diminish rate-dependent block, physostigmine's indiscriminate use and the failure to adequately address sodium channel blockade and the pathophysiology of CA poisoning were associated with bradydysrhythmias including asystole, seizures, and deaths [82, 83]. In animal models, physostigmine failed to abolish dysrhythmias, decreased blood pressure, and enhanced CA toxicity at high doses [84].

Decreased heart rate may increase the QT interval and predispose to *torsades de pointes*. Because of this, physostigmine is not indicated for the treatment of patients poisoned with sodium channel-blocking antidysrhythmics, CAs, or other agents when sodium channel blockade is clinically and/or electrocardiographically evident. Attempts to decrease heart rate with beta antagonists, including those with mild positive inotropy, were equally futile in canine studies. Despite narrowing the QRS, hypotension and death ensued [79, 85].

Bradydysrhythmias suggest severe sodium channel antidysrhythmic poisoning. In the presence of severe bradycardia, a wide QRS complex, and hypotension, it is recommended – based on anecdotal, theoretical, experimental, and clinical considerations – that intravenous (IV) epinephrine be administered by continuous infusion and titrated to effect if intravenous sodium bicarbonate administration does not elicit an immediate beneficial response (Grade II-1 evidence) [86–89]. While transcutaneous or transvenous pacing may be attempted in the initial management of significant bradydysrhythmia, results are generally unsatisfying due to persistent negative inotropy. There is no compelling theoretical support or clinical evidence for the use of atropine in the treatment of sodium channel blockade-induced bradydysrhythmias.

Initial treatment of sodium channel antidysrhythmic-induced ventricular dysrhythmia is sodium bicarbonate boluses. In the face of ventricular dysrhythmias, further exposure to class IA or IC agents would be anticipated to worsen myocardial toxicity from sodium channel blockade. Based on the on-off receptor kinetics of class IB antidysrhythmics and minimal effects on phase 0 of the action potential in nondiseased hearts, lidocaine has been suggested as the

antidysrhythmic drug for the treatment of ventricular dysrhythmias from class IA or IC agents or CAs (Grade III recommendation) [90]. Canine studies showed transient suppression of ventricular ectopy with lidocaine, complicated by hypotension [68]. Lidocaine reversed QRS widening and slowed ventricular conduction in cocaine-poisoned guinea pig hearts [70]. In a series of CA poisoned patients, lidocaine infusions (2.0 ± 0.5 mg/min) suppressed frequent ventricular ectopy, without adverse events [91]. Lidocaine presents a reasonable option in patients with dysrhythmias that persist after sufficient sodium bicarbonate therapy. It should not be given to patients suffering toxicity from other type IB antidysrhythmics.

Magnesium can be considered as a follow-on agent. In cyclic antidepressant poisoning, one small, controlled study (Grade II-2 evidence) utilizing intravenous magnesium 1 g every 6 h [92] and several case reports [93–95] utilizing various dosing strategies have demonstrated effective treatment of ventricular dysrhythmias, decreased ICU stay, and decreased mortality. Intravenous magnesium has been reported to abolish digitalis-associated dysrhythmias (Grade III evidence) [96, 97]. Magnesium is also reported to reduce the toxicity of drugs with class III properties (Grade II-2 evidence) [98]. It would be reasonable to administer intravenous magnesium in cases of persistent dysrhythmia, in patients unresponsive to standard therapy, or in poisoning with agents with significant class III properties.

Hypotension

Patients with hypotension can be treated with judicious crystalloid boluses, unless they are contraindicated (e.g., pulmonary edema in the failing heart). Adequate treatment with hypertonic sodium bicarbonate is a priority. Murine studies of cyclic antidepressants demonstrated a survival benefit from sodium bicarbonate independently and additively to benefit from inotropic drug treatments, with epinephrine treatment superior to norepinephrine [86, 87]. Norepinephrine effectively resuscitated cyclic antidepressant poisoned canines [99]. In controlled human studies in a

dose-dependent fashion, epinephrine infusion partially or completely reverses quinidine's antiarrhythmic drug effects and prolongation of the ventricular refractory period; epinephrine partially reversed the effects of amiodarone (Grade II-1 evidence) [88, 89]. Epinephrine, with diazepam and mechanical ventilation, demonstrated improved outcomes of previously fatal human chloroquine poisonings (Grade II-2 evidence) [100]. A FOCUS examination may help guide whether positive inotropes or agents with more vasoconstrictive properties are needed.

Given the limitations of existing therapy and the lack of specific antidotes, antidysrhythmic-induced cardiovascular shock remains a leading cause of death [33, 101]. Definitive conclusions regarding the efficiency and indications for "extraordinary measures" are unlikely to emerge from available case reports and case series. However, "extraordinary measures" successfully applied to moribund patients poisoned with cardiotoxins have included prolonged manual chest compressions or "thumper" devices, cardiac pacing, intra-aortic balloon pump, or extracorporeal life support (ECLS) with extracorporeal membrane oxygenation (ECMO) or emergency cardiopulmonary bypass (Grade III recommendation) [31, 101, 102]. Extracorporeal life support in acute cardiogenic shock provides the opportunity to recover cardiac function [103] and permit toxin redistribution away from the cardiac compartment to permit elimination to occur.

High-dose Insulin Euglycemia (HIE) Therapy

For treatment of severe poisoning with class II and class IV agents, high-dose insulin with sufficient supplemental dextrose to ensure euglycemia has emerged as a first-line therapy (Grade III evidence) [104]. HIE would thus be recommended for class II agents which display sodium channel blockade (Table 2) (Grade III evidence) [104]. Insulin dosing consists of a bolus of 0.5–1 units per kg, followed by a 1–10 units per kg per hour continuous insulin infusion [105]. In light of propafenone's beta-adrenergic antagonism,

following successful HIE application in a refractory case of human propafenone poisoning, HIE was found to improve survival, improve central venous oxygen saturation, and delay the hemodynamic and electrocardiographic consequences of propafenone toxicity in murine models [106, 107]. Application of this therapy to poisoning with class I agents with beta-adrenergic antagonism, such as propafenone, would need to take into account the potential side effects of hypoglycemia and electrolyte imbalance (e.g., hypokalemia). Applying the available human (Grade III) evidence for class II agents and animal models, HIE may be considered in propafenone poisoning unresponsive to current treatment methods.

Intravenous Lipid Emulsion

Intravenous lipid emulsion (ILE) (typically 20%), also known as intravenous fat emulsion therapy or "rescue," has been incorporated in guidelines for treatment of cardiovascular collapse associated with Local Anesthetic Systemic Toxicity (LAST) [108]. Many sodium channel blockers possess a distribution constant log D – a better descriptor of the lipophilicity at physiological pH – suggestive of a role for ILE (Table 2). Indeed, case reports document ILE success in resuscitating patients rendered moribund by antidysrhythmic poisoning [109]. However, consensus reviews of ILE and its adverse effects in LAST and non-LAST poisoning highlight the low quality of human data (Grade III) [110–112]. ILE administration too early after oral poisoning has the potential to facilitate GI tract drug absorption or redistribution, exacerbating toxicity and, in theory, compromising the efficacy of lipid-soluble antidotes and concomitant therapies [113]. In swine and lapine models, intravenous lipid emulsion was inferior to sodium bicarbonate and no better than volume resuscitation in CA toxicity, no better than sodium bicarbonate in diphenhydramine toxicity, and no better than sodium bicarbonate in flecainide toxicity [114–117]. Intravenous lipid emulsion could be attempted when conventional therapies have failed. However, current evidence does not support its routine use in sodium channel blocking agent toxicity. Of note, multiple common

analytes can be markedly altered by lipemia after lipid administration [118]. ILE is also reported to cause fat emulsion agglutination, stopcock cracking, clogging and associated malfunction of the membrane oxygenator, and blood clot formation in ECMO circuits [119].

Seizures

Animal data derived from sodium channel blocking cyclic antidepressants and human case reports suggest that seizure treatment with standard antiepileptic drugs other than phenobarbital is not helpful and potentially life-threatening (Grade III recommendation) [85, 120–122]. The cardiac repercussions of seizures associated with sodium channel blockade are severe and include QRS widening, hypotension, acidemia, and cardiovascular collapse [40, 123]. Aggressive, early management with benzodiazepines, barbiturates, or propofol should be a priority.

Hypoglycemia

Given the adverse neurological effects of neuroglycopenia, hypoglycemia should be aggressively managed with age-appropriate concentrated dextrose, 0.5–1.0 g/kg. Octreotide has been successfully applied to suppress quinine-induced hyperinsulinemia and refractory hypoglycemia (Grade III evidence) [124].

Indications for ICU Admission in Sodium Channel-Blocking Antidysrhythmics Poisoning

- Hemodynamic instability and/or shock
- Bradydysrhythmias
- Ventricular dysrhythmias
- Conduction defects (2nd-, 3rd-degree atrioventricular block; intraventricular conduction delay)
- Respiratory failure
- Seizures
- Persistent hypoglycemia

- Moderate to severe anticholinergic toxicity
- Significant coingestants and/or other compromising comorbid medical conditions

Disposition

Although not systematically studied, reviews suggest that patients poisoned with nonsustained-release sodium channel-blocking antidysrhythmics can usually be expected to become symptomatic within 6 h after ingestion, and much sooner after parenteral exposure [31, 78]. The vast majority of patients who manifest no clinical signs of toxicity after 6 h of monitored observation and have consistently normal ECG findings are most likely safe for medical clearance. Ingestion of any of the sustained-release sodium channel-blocking antidysrhythmic formulations, uncertainty regarding the exact formulation ingested, coingestants of concern, or coingestants that alter gut motility may warrant 24 h of cardiac-monitored observation.

Key Points

- Clinical toxicity is usually evident within 6 h of exposure to a nonsustained-release formulation; ingestion of a sustained-release formulation may result in delayed onset and/or prolonged toxicity
- ECG evidence of sodium channel blockade-induced toxicity includes hypotension, bradydysrhythmias, atrioventricular and intraventricular conduction delays, and ventricular tachydysrhythmias
- Other cardiotoxic manifestations associated with sodium channel-blocking antidysrhythmics include prolonged QT/torsades de pointes (potassium efflux blockade) and sinus tachycardia (antimuscarinic effects, e.g., quinidine)
- Noncardiovascular toxicity associated with sodium channel-blocking antidysrhythmic drugs includes central and peripheral

(continued)

anticholinergic syndrome, seizures, and hypoglycemia

- Appropriate treatment of toxicity includes airway/ventilatory support, cautious IV volume expansion, hypertonic sodium bicarbonate (1-mEq/kg IV boluses to an arterial pH of 7.45–7.55), intravenous vasopressors (norepinephrine, epinephrine), intravenous lidocaine for ventricular tachydysrhythmias, and hypertonic (3%) saline for hemodynamic instability or dysrhythmia refractory to other treatments
- Intraaortic balloon pump or ECLS can be considered for severe refractory cardiogenic shock

Sodium nitroprusside (SNP) entered into clinical practice in 1955 and gained popularity as a vasodilator for hypertensive emergencies because of its rapid onset of action and short duration, which allowed for bedside titration to the desired effect [1]. The introduction of a freeze-dried preparation in 1974 was followed by an additional increase in popularity, and it continued to gain favor for producing controlled hypotension during anesthesia and afterload reduction during low cardiac output states. Availability of alternative agents has more recently limited use of SNP for hypertensive emergencies. However, novel applications, such as for the treatment of schizophrenia, are under investigation [2].

SNP therapy can result in two major distinct toxic syndromes: cyanide toxicity and thiocyanate (SCN^-) toxicity [3]. Each of these two disorders differs in risk factors, pathophysiology, signs and symptoms, diagnostic strategies, methods of prevention, and treatment. Cyanide toxicity is described in greater detail in the chapter on cyanide and is covered more superficially here.

Cyanide Toxicity from Sodium Nitroprusside**Chemistry and Pathophysiology**

The structure of SNP (Fig. 1) explains why desired vasodilation and cyanide toxicity may result from its use. SNP contains about 50%

cyanide by weight. Early investigators attributed SNP's *in vivo* decomposition to hydrocyanic acid (HCN) to a reaction with oxyhemoglobin. It has been accepted for many years, however, that each SNP molecule decomposes when it reacts with sulfhydryl groups on endothelial cells [4, 5], releasing nitric oxide (producing vasodilation) and five cyanide moieties (Fig. 2).

When solutions of SNP are exposed to intense sunlight, they decompose relatively quickly to release cyanide. Solutions of SNP are relatively

stable, however, when exposed to artificial light. When protected from light, acidic or neutral solutions of SNP remain stable for months to years. It is unnecessary to prepare fresh solutions of SNP every 4 h if the solution has been protected from bright sunlight [3]. The infusion of SNP in the same line as intravenous solutions containing sulfhydryl groups (e.g., amino acid solutions, *N*-acetylcysteine) also would be expected to accelerate its breakdown to cyanide [5, 6].

At physiologic pH, all cyanide exists as HCN, and HCN has two main fates. First, HCN can be detoxified by being transsulfurated to thiocyanate (SCN^-), probably through several mechanisms. SCN^- undergoes renal excretion with an elimination half-life of 2.7 days in patients with normal renal function (see Fig. 2) [7]. Second, HCN can move into tissue and mitochondria to bind to the binuclear copper-iron center of cytochrome oxidase, where it inhibits electron transport, oxygen consumption, and oxidative phosphorylation. Because oxidative phosphorylation is a major buffer of protons, inhibition of cytochrome

Fig. 1 Chemical structure of sodium nitroprusside

Fig. 2 The fate of sodium nitroprusside (SNP). Nitroprusside reacts with endothelial sulfhydryl groups to release nitric oxide (producing vasodilation) and five cyanide moieties (HCN). In the presence of adequate stores of thiosulfate, HCN is transsulfurated to form thiocyanate (SCN^-), which is excreted in the urine with a half-life of 2.7 days in patients with normal renal function. Inadequate

thiosulfate stores lead to accumulation of HCN, which can move into tissue to produce cyanide toxicity. Large doses of nitroprusside, prolonged infusions, and renal insufficiency can cause the accumulation of SCN^- , which produces a separate toxic syndrome. If SNP routinely is coin fused with sodium thiosulfate, HCN does not accumulate, and cyanide toxicity is prevented

oxidase by cyanide is accompanied by metabolic acidosis. Hyperlactatemia reflects increased glycolytic adenosine triphosphate production and a shift in the redox potential.

An important, and probably the dominant, sulfur donor for detoxification of HCN is thiosulfate ($\text{S}_2\text{O}_3^{2-}$). A healthy adult seems to possess enough thiosulfate to metabolize about 50 mg of SNP over the short term [8]. Patients coming off cardiac bypass or receiving diuretics may have lower plasma thiosulfate concentrations and might be predisposed to cyanide toxicity from a given dose of SNP, although this has never been proved. Short-term starvation, such as after other types of surgery, has been associated with increases in circulating thiosulfate levels [8], probably as a result of mobilization of sulfur-containing amino acids from skeletal muscle catabolism. There are no data supporting the contention that hepatic insufficiency predisposes to SNP-induced cyanide poisoning. Animals with hepatic damage detoxify HCN without difficulty [9]. In dogs, renal insufficiency is associated with lower circulating cyanide levels for a given SNP infusion rate.

Pharmacokinetics

Absorption of SNP is instantaneous and complete with intravenous infusion [5]. In blood, SNP is found almost wholly in plasma, with little to none in blood cells. This fact suggests that the nitroprusside anion distributes mainly to the extracellular space. The rapid breakdown of nitroprusside through interactions with sulfhydryl groups results in an elimination half-life of about 2 min, explaining the requirement of a continuous infusion and the ease with which infusion rates may be titrated to clinical effects.

Clinical Findings and Toxic Doses

Cyanide poisoning has resulted from short-term and long-term infusions of SNP [10–13]. When used as *short-term* infusions, such as those used

during anesthesia, circulating HCN concentrations begin to increase when the total dose (not infusion rate) of SNP exceeds 0.5–1.5 mg/kg [14, 15]. For *long-term* infusions, such as those used in the intensive care unit, circulating HCN concentrations begin to increase when SNP infusion rates exceed approximately 2 $\mu\text{g/kg/min}$ [3, 5]. Vesey and Cole [16] showed that on average, SNP infusion rates less than about 4 $\mu\text{g/kg/min}$ would not be expected to produce toxic plasma cyanide concentrations. Toxic HCN concentrations may be reached within a few hours when infusion rates exceed 5–10 $\mu\text{g/kg/min}$, but this is not always the case. Cyanide toxicity also may not appear until several days after beginning a SNP infusion.

The signs and symptoms of cyanide poisoning are described in detail in the chapter devoted to cyanide. Briefly, cyanide toxicity is characterized by central nervous system and cardiovascular dysfunction and metabolic acidosis. All of these abnormalities are seen commonly in critically ill patients, making it sometimes difficult to discern whether cyanide toxicity accounts for a patient's declining course. Central nervous system dysfunction includes agitation, confusion, convulsions, coma, and cerebral death. Cardiovascular findings comprise tachycardia, bradycardia, hypotension, and, sometimes, early hypertension. SNP and HCN produce vasodilation and a decline in systemic vascular resistance. Serial measurements of cardiovascular parameters with a pulmonary artery catheter reveal a decrease in oxygen consumption and, if cardiac output and hemoglobin concentrations remain unchanged, an increase in mixed venous oxygen content. There are no established values, however, for oxygen consumption or mixed venous oxygen content that provide reliable positive and negative predictive values for the presence of cyanide poisoning. A low systemic vascular resistance, anion gap metabolic acidosis, elevated arterial lactate concentrations, and depressed oxygen consumption are typical of SNP-induced cyanide poisoning, as are sepsis, hepatic failure, toxic shock syndrome, and systemic inflammatory response syndrome.

Diagnosis

The diagnosis of cyanide poisoning from SNP should be considered whenever central nervous system dysfunction, metabolic acidosis, and cardiovascular dysfunction accompany SNP infusion rates greater than about 4 $\mu\text{g/kg/min}$. Theoretically, however, infusion rates greater than 2.5 $\mu\text{g/kg/min}$ over many hours might be capable of producing HCN toxicity in an exceptional patient. Serious cyanide poisoning always results in metabolic acidosis, unless the patient is receiving alkaline infusions (e.g., sodium bicarbonate) or has a significant baseline metabolic alkalosis. Arterial lactate concentrations are elevated. Most patients with cyanide toxicity do not have unusually pink or bright red skin or blood; many are cyanotic. The presence of bright red skin or unusually bright red venous blood or retinal veins suggests the possibility of cyanide poisoning, however. Hypothermia commonly is noted in comatose victims of cyanide toxicity. An abnormal odor, including that of bitter almonds, would not result from SNP-induced cyanide poisoning.

It has been noted anecdotally that the onset of cyanide poisoning is accompanied by an increase in blood pressure and what seems to be resistance to SNP-induced vasodilation. Whether this is true and serves as a useful clinical clue or whether simply the higher doses of SNP result in cyanide toxicity has not been clarified in controlled trials with serial measurements of red blood cell or plasma cyanide concentrations. Resistance to SNP certainly can occur in the absence of cyanide poisoning.

Whole-blood cyanide concentrations, as performed at most reference laboratories, commonly are elevated falsely in patients receiving long-term SNP infusions because of elevated plasma SCN^- concentrations (see ► Chap. 97, “Cyanide: Hydrogen Cyanide, Inorganic Cyanide Salts, and Nitriles”) [17], and this has led to the misdiagnosis of cyanide poisoning from SNP in patients without evidence of cyanide toxicity [18, 19].

Plasma cyanide concentrations would be more helpful but are difficult to measure accurately. *Red blood cell* cyanide concentrations are easier to

measure and correlate well with severity of cyanide poisoning. In general, metabolic disturbances from cyanide poisoning appear with red blood cell cyanide concentrations of about 1 mg/L (approximately 40 mmol/L). Obvious cyanide poisoning is evident with red blood cell HCN concentrations of 5 mg/L (approximately 200 mmol/L) [18].

Many laboratories do not offer measurement of red cell cyanide concentrations, and results from any of these tests usually do not return for hours to days after the specimen is obtained and sent. The delay in obtaining results, false elevation in whole-blood cyanide concentrations in many patients receiving SNP, and difficulty in obtaining red blood cell cyanide concentrations or accurately measured plasma cyanide concentrations limit the practical value of cyanide bioassay in establishing a timely diagnosis of cyanide toxicity.

Most patients with SNP-induced cyanide poisoning have nontoxic serum SCN^- concentrations, although they may be elevated above the reference range. Serum SCN^- levels are not helpful in establishing or excluding the diagnosis of cyanide toxicity.

Prevention

Numerous studies have shown that the coinfusion of sodium thiosulfate with SNP prevents increases in circulating HCN concentrations, even with SNP infusion rates approaching 20 $\mu\text{g/kg/min}$ [5, 20]. Each 100 mg of SNP should be mixed with 1 g of sodium thiosulfate [3]. These mixtures are stable for at least 7 days when protected from light [20]. Each 1 g of sodium thiosulfate contains 12.6 mmol of sodium.

Cyanide poisoning from SNP becomes virtually impossible if the correct dose of sodium thiosulfate has been coinfused. Patients receiving mixtures of thiosulfate and nitroprusside experience more rapid detoxification of HCN to SCN^- , however, and higher plasma SCN^- levels. SCN^- toxicity is rarely a problem and

can be monitored easily with measurement of serum or plasma SCN^- concentrations.

Treatment

SNP should be discontinued in patients suspected of having cyanide toxicity. The SNP infusion can be restarted if SNP is mixed or coin fused with sodium thiosulfate as described earlier. Patients with serious cyanide poisoning (e.g., coma, hypotension, moderate-to-severe metabolic acidosis) should receive either sodium nitrite and sodium thiosulfate or hydroxocobalamin or dicobalt EDTA as described in the chapter on cyanide or whichever cyanide antidote is locally available. One should begin treating promptly on the basis of clinical suspicion, rather than waiting for results of blood cyanide concentrations. In a nonanemic adult, 300 mg of sodium nitrite intravenously should be infused, followed by 12.5 g intravenously of sodium thiosulfate if using the Nithiodote[®] kit. If using the Cyanokit[®], 5 g hydroxocobalamin should be infused over 15 min. Patients who are only mildly symptomatic from cyanide toxicity and in whom induction of methemoglobinemia with sodium nitrite may be dangerous (e.g., those with severe anemia) are likely to improve with discontinuance of SNP and infusion of sodium thiosulfate alone.

Vesey and Cole [16] showed that accurately measured red blood cell and plasma HCN concentrations decrease with a half-life of about 30 min after SNP is halted and decrease with a half-life of about 10 min if thiosulfate (without nitrite) is also given. These HCN concentrations were not in the highly toxic range, however, and it is not known if this half-life can be extrapolated to much higher HCN levels.

Thiocyanate Toxicity from Sodium Nitroprusside

Most of the HCN released from SNP undergoes transsulfuration to form SCN^- , which is excreted in the urine with an elimination half-life of 2.7

days in patients with normal renal function and 9 days in patients with severe renal insufficiency [7, 16]. Because of its long elimination half-life, SCN^- can accumulate in patients receiving SNP infusions over several days.

Clinical Findings and Toxic Doses

Most knowledge concerning SCN^- toxicity and the definition of toxic plasma concentrations has resulted from past extensive use of oral SCN^- salts in the treatment of hypertension. This older literature describes SCN^- toxicity as comprising abdominal colic, vomiting, weakness, rash, tinnitus, and hypothyroidism. More severe toxicity results in delusions, agitation, disorientation, tremor, convulsions, coma, and death.

The mechanism by which SCN^- produces toxicity is unknown. The older literature described the enzymatic conversion of SCN^- to HCN, but this now is known to have been an *in vitro* artifactual phenomenon. In contrast to cyanide poisoning, SCN^- toxicity is not accompanied by a metabolic acidosis in the absence of other causes, such as convulsions or shock.

Diagnosis

Although serum or plasma SCN^- concentrations do not assist in establishing or excluding the diagnosis of cyanide poisoning, they are of diagnostic utility with regard to SCN^- toxicity. Normal plasma SCN^- concentrations in non-smokers are approximately less than 4 mg/L (<0.4 mg/dL [<0.07 mmol/L]), whereas smokers, who inhale HCN in cigarette smoke, have plasma SCN^- levels of less than 8 mg/L (<0.8 mg/dL [<0.14 mmol/L]). Even serum or plasma SCN^- concentrations of 100 mg/L (10 mg/dL [1.7 mmol/L]) are not accompanied by significant toxicity. Serious SCN^- toxicity occurs when plasma SCN^- concentrations are greater than 150–200 mg/L (>15–20 mg/dL [>2.6 –3.4 mmol/L]) [16].

Prevention of and Monitoring for Toxicity

Patients receiving long-term infusions of SNP commonly have plasma SCN^- concentrations above normal reference values [16]. Plasma concentrations only rarely reach a level associated with systemic toxicity, however. SCN^- toxicity is not expected until the total SNP dose infused (not infusion rate) exceeds about 70 mg/kg [16]. In patients with normal renal function, SCN^- toxicity could occur in 7–14 days, whereas in patients with renal insufficiency, SCN^- toxicity can occur as early as 3–6 days [5].

Patients receiving coinfusions of sodium thiosulfate with SNP form SCN^- more readily and develop higher plasma SCN^- concentrations for a given SNP infusion rate. SCN^- toxicity remains uncommon, however, when SNP infusions are limited to 1–2 days in patients with renal failure or to 6–7 days in patients with normal renal function.

Treatment

Several authors have described effective removal of SCN^- with hemodialysis [21, 22]. Hemodialysis is considered the treatment of choice (level III evidence) for patients with severe SCN^- toxicity, especially in the presence of renal insufficiency.

Common Errors in the Management of Sodium Nitroprusside Toxicity

Using sodium nitroprusside without coinfusion of sodium thiosulfate

Failing to recognize falsely elevated whole-blood cyanide concentrations in many patients receiving sodium nitroprusside

Using serum or plasma thiocyanate levels to diagnose or exclude cyanide toxicity

Believing that most patients with cyanide poisoning have bright red skin or blood or exude a bitter almond odor

Believing it is necessary to mix a new bag of sodium nitroprusside every 4 h when the solution is covered and protected from bright sunlight

Special Populations

Pregnant Patients

Case reports and series document successful use of SNP for short infusions (e.g., during aneurysm clipping), with low total doses (e.g., ≤ 60 mg) and with low infusion rates (e.g., $< 3 \mu\text{g/kg/min}$) in pregnant women and gravid ewes [23–26]. Concern has been raised appropriately, however, with regard to the induction of fetal cyanide toxicity during maternal use of SNP. SNP infusions in gravid ewes can produce increases in maternal and fetal red blood cell cyanide concentrations [27]. Nitroprusside crosses the ovine placenta to produce equal concentrations in fetal and maternal blood [28]. Hydrogen cyanide, a small, lipophilic molecule, also crosses the placenta easily.

In gravid near-term ewes, the coinfusion of sodium thiosulfate with SNP prevents increases in maternal and fetal cyanide concentrations [28]. In this model, thiosulfate does not cross the placenta to enter the fetal circulation [29]. Maternally administered thiosulfate prevents ovine fetal cyanide toxicity by keeping maternal HCN concentrations low, allowing HCN to diffuse from the fetal circulation back into the maternal circulation for detoxification [29]. Fetal SCN^- concentrations do not increase during short-term infusions of maternal SCN^- in the ewe model [28].

No studies examining fetal and maternal HCN concentrations in pregnant women receiving SNP compared with pregnant women receiving SNP mixed with thiosulfate have been conducted. Given the safety and lack of adverse effects associated with sodium thiosulfate combined with data from ewe studies, it is recommended that the use of SNP in pregnant women always be

accompanied by coinfusion of sodium thiosulfate as described previously for nonpregnant patients.

Key Points in Sodium Nitroprusside Toxicity

1. SNP therapy produces two toxic syndromes: cyanide poisoning and thiocyanate toxicity.
2. Doses of SNP for short-term administration (e.g., 1–2 h) should not exceed 0.5–1.5 mg/kg to prevent cyanide toxicity.
3. Circulating cyanide concentrations begin to increase when long-term SNP infusions (>2 or 3 h) exceed about 2 µg/kg/min. Cyanide toxicity may occur when infusion rates exceed about 4 µg/kg/min.
4. Cyanide toxicity may occur within minutes to hours with large doses or fast infusion rates or may be delayed for hours to days with lower infusion rates.
5. The clinical picture of SNP-induced cyanide poisoning is similar to that of septic shock, liver failure, and other disorders (e.g., low systemic vascular resistance, hypothermia, lactic acidosis, lethargy/coma, tachycardia and hypotension, decreased oxygen consumption).
6. SNP-induced cyanide poisoning is prevented completely with coinfusion of sodium thiosulfate; 1 g of sodium thiosulfate should be mixed with each 100 mg of SNP.
7. SNP-induced cyanide toxicity is treated in an adult by stopping the SNP infusion and administering 300 mg of sodium nitrite and 12.5 g of sodium thiosulfate intravenously or by giving 5 g hydroxocobalamin intravenously.
8. Whole-blood cyanide concentrations rarely return quickly enough to be helpful and commonly are falsely elevated in patients receiving SNP infusions.

9. Serum or plasma thiocyanate concentrations are nontoxic in most patients with cyanide toxicity and are not helpful in establishing or excluding the diagnosis of cyanide poisoning.
10. Thiocyanate accumulates over days to weeks to produce thiocyanate toxicity. Thiocyanate toxicity is prevented by limiting total SNP doses to <70 mg/kg and by monitoring serum or plasma thiocyanate concentrations.
11. Moderate-to-severe thiocyanate toxicity (e.g., confusion, coma, rash, abdominal pain, seizures) does not appear until serum or plasma thiocyanate concentrations exceed about 150–200 mg/L (15–20 mg/dL).
12. Severe thiocyanate toxicity is treated with hemodialysis, especially in patients with renal insufficiency.

Sympathomimetics constitute a large group of drugs with a spectrum of uses that range from over-the-counter cough and cold preparations to critical care medications. Their clinical effects are similar and theoretically should be predictable based on an understanding of the specific pharmacology of the drugs. However, because of the complexity of the autonomic nervous system and its responses to physiologic changes within the body, the actual clinical effects of these drugs vary and may be unpredictable.

Chemistry and Biochemistry of Sympathomimetic Agents

β -Phenylethylamine, the parent compound of the sympathomimetic amines, consists of a benzene ring and ethylamide side chain (Fig. 1). Substitutions are possible on the aliphatic ring, the α and β carbon, or the terminal amino group to yield a variety of compounds with sympathomimetic activity. Less polar molecules are more lipophilic and possess a greater tendency to cross the blood–brain barrier, resulting in central effects. Examples of such sympathomimetic amines are ephedrine and amphetamines. The more polar compounds (e.g., epinephrine, norepinephrine, and isoproterenol) cross the blood–brain barrier poorly, and their effects are peripheral (see Fig. 1).

Pathophysiology

The sympathomimetic toxidrome, addressed in detail in ► [Chap. 25, “Sympathomimetic Syndrome,”](#) is technically a misnomer. Excess autonomic stimulation and agents that mimic this process produce the clinical syndrome typically described as “sympathomimetic.” Prediction of the clinical effects of particular adrenergic agonists is possible based on their preferred adrenergic binding activity; their ability to cross the blood–brain barrier; and their direct, indirect, or mixed activity. Following an overdose, the receptor specificity may be diminished and the clinical effects of the various agents may become less predictable. The sequelae of sympathomimetic overdose are most significantly related to the cardiovascular and neurological systems and include, respectively: cardiac dysrhythmia, hypertension or hypotension; end-organ injury such as myocardial ischemia and infarction; and psychomotor agitation, stroke, and seizure.

The endogenous catecholamines include epinephrine, norepinephrine, and dopamine. These neurotransmitters, released from adrenergic and dopaminergic nerve endings, from the adrenal medulla, and locally within the sympathetic nervous system, are involved in numerous physiologic functions, including homeostasis and response to stressors. The actions of catecholamines are terminated rapidly by reuptake into

nerve terminals with metabolic degradation by monoamine oxidase (MAO) or by repackaging in vesicles (Fig. 2). Alternatively, termination of catecholamine activity may result after diffusion from the synaptic cleft with subsequent degradation at extraneuronal sites by catechol *O*-methyltransferase (COMT).

Synthetic sympathomimetic amines are structural analogues of the endogenous catecholamines. They lack several crucial hydroxyl groups, a property that increases their oral bioavailability by reducing their hepatic metabolism by COMT. In some cases, substitutions on the phenyl group (see Fig. 1) confer MAO resistance to these agents.

Adrenergic Receptors

Adrenergic receptors are broadly classed as α and β , but numerous subtypes exist. The clinically relevant types addressed here are α_1 , α_2 , β_1 , β_2 , and β_3 (Table 1). α_1 -Adrenergic receptors are postsynaptic and cause contraction of smooth muscle with various clinical effects. α_2 -Receptors are primarily presynaptic and function in an autoregulatory capacity. Synaptic norepinephrine inhibits further release of presynaptic norepinephrine by feedback inhibition. Postsynaptic α_2 -receptors share many of the properties of α_1 -receptors but also mediate a few unique effects (see Table 1).

Fig. 1 Chemical structure of phenylethylamine and related sympathomimetics

Fig. 2 Prejunctional and postjunctional sites of action of drugs that modify noradrenergic transmission at a sympathetic neuroeffector junction. L-Tyrosine is actively transported into the axoplasm of the neuron, where it is converted first to L-dopa by tyrosine hydroxylase (TH) and then to dopamine by aromatic L-amino acid decarboxylase (ALAAD). Dopamine is actively transported into synaptic vesicles, where it is converted by dopamine β -hydroxylase (DBH) to norepinephrine (NE). The arrival of a nerve action potential at the varicosity causes the influx of calcium ions, which promotes the exocytotic release of NE into the neuroeffector junction, where NE can activate receptors on postjunctional smooth muscle or glandular cells (α_1 or α_2) or cardiac cells (β_1) or on the prejunctional neuronal membrane (α_2). Activation of the α_2 -receptor inhibits the further release of NE. The action of NE is terminated by transport back into the varicosity, uptake 1.

In the synapses, NE can be stored in the synaptic vesicle or metabolized by monoamine oxidase (MAO) to inactive deaminated products. NE also is lost from the neuroeffector junction by diffusion and by transport into the postjunctional cell, where it is metabolized to normetanephrine by COMT. Drugs that enhance or mimic noradrenergic transmission (1) facilitate release (e.g., amphetamine), (2) block reuptake (e.g., cocaine), and (3) are receptor agonists (e.g., phenylephrine). Drugs that reduce noradrenergic transmission (1) inhibit synthesis (e.g., 1a, α -methyltyrosine; 1b, carbidopa; 1c, disulfiram), (2) disrupt vesicular storage (e.g., reserpine), (3) inhibit release (e.g., guanethidine), and (4) are receptor antagonists (e.g., phentolamine) (From Brody TM, Larner J, Minneman KP [eds]: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, with permission)

β_1 -Receptors are located primarily on the myocardium and are involved in cardiovascular stimulation. β_2 -Receptors mediate numerous clinical effects, but the most important are related to smooth muscle relaxation in the vasculature and bronchioles. β_3 -Receptors are located in adipose tissue, the

gallbladder and urinary bladder. The main effects are relaxation of the urinary bladder, and lipolysis and thermogenesis in adipose tissue (see Table 1).

The endogenous catecholamines dopamine, epinephrine, and norepinephrine are nonspecific adrenergic agonists; they stimulate α -adrenergic

Table 1 Adrenoreceptor subtypes

Adrenoreceptor type	Tissue	Response
α_1	Most smooth muscle	Contraction
	Hepatic	Glycogenolysis, gluconeogenesis
	Intestinal smooth muscle	Relaxation
	Pupillary dilator muscle	Contraction (dilates pupil)
α_2	Vascular smooth muscle	Contraction
	CNS adrenoreceptors	Multiple effects, including lowering blood pressure
	Nerve terminals	Inhibits norepinephrine release
	Fat cells	Inhibits lipolysis
	Pancreatic β cells	Decreases insulin secretion
β_1	Cardiac	Increases inotropy and chronotropy
β_2	Smooth muscle	Relaxation
	Skeletal muscle	Glycogenolysis
β_3	Hepatic	Glycogenolysis, gluconeogenesis
	Bladder smooth muscle	Relaxation
	Adipose	Lipolysis, thermogenesis

CNS central nervous system

and β -adrenergic receptors. When administered exogenously all are predominantly peripherally acting and do not exert significant central nervous system (CNS) effects. Epinephrine and norepinephrine are direct-acting sympathomimetics, meaning they bind to and stimulate adrenergic receptors. They differ slightly, however, in their receptor selectivity. Most significantly, epinephrine is a potent β -adrenergic agonist, whereas norepinephrine is in all practicality a pure α -adrenergic agonist. Clinically, epinephrine has potent chronotropic and inotropic activity and norepinephrine has less effect on cardiac contractility or rate. In doses >0.1 mcg/kg/min, both epinephrine and norepinephrine cause an increase in peripheral vascular resistance. Epinephrine also exerts many metabolic effects and hormone-like effects on secretory glands

that norepinephrine does not (Table 2). Dopamine acts indirectly by affecting increased release of norepinephrine from the presynaptic neuron. At increased serum concentrations, dopamine may exert mixed, direct, and indirect activity. Several distinct types of dopamine receptors mediate the peripheral effects of dopamine. At low doses, <3 mcg/kg/min, dopamine's primary effect is vasodilatory rather than vasoconstrictive. Stimulation of D_1 receptors results in vasodilation, particularly in the renal, mesenteric, and coronary vasculature. At increasing doses >3 mcg/kg/min, dopamine stimulates β_1 -adrenergic receptors, with resulting increase in cardiac chronotropy and inotropy, and at doses >5 mcg/kg/min, stimulates α_1 -receptors, resulting in vasoconstriction.

The synthetic sympathetic amines are a large group of agents each with a unique combination of pharmacologic effects. Their mechanism of action is similar to the endogenous catecholamines, but because of unique structural and chemical qualities, they have unique pharmacologic and clinical properties. As a group, these agents have much greater CNS penetration than the catecholamines, although there are tremendous variations within the group. For example, methamphetamine is a more potent CNS stimulant than other amphetamine congeners, such as ephedrine, owing to its enhanced CNS penetration and to receptor binding potency.

Specific agents can be classified by their activities at α -receptors and β -receptors and their subtypes or alternatively classified according to their direct, indirect, or mixed action as adrenergic agents. Because the clinical effects of these agents vary based on their receptor selectivity, this is the framework used for discussion. These effects from amphetamines and their derivatives are discussed in ► [Chap. 72, "Amphetamines and Their Derivatives."](#)

Agents with Combined α -Adrenergic and β -Adrenergic Activity

Epinephrine, Norepinephrine, and Dopamine

Poisoning from epinephrine, norepinephrine, and dopamine may result from inhalational,

Table 2 Method of action and adrenoceptor effects of sympathomimetics

Drug	Direct, indirect, or mixed activity	Predominant adrenoceptor effect	Comments
Dopamine	Mixed	β_1	Dopaminergic activity as well
Dobutamine	Direct	β_1	
Epinephrine	Direct	$\alpha_1, \alpha_2, \beta_1, \beta_2$	
Norepinephrine	Direct	α_1, α_2	
Ephedrine	Mixed	$\alpha_1, \alpha_2, \beta_1, \beta_2$	
Pseudoephedrine	Mixed	$\alpha_1, \alpha_2, \beta_1, \beta_2$	
Mitodrine	Direct	α_1	
Synephrine	Direct	α_1	
Phenylephrine	Direct	α_1	
Methoxamine	Direct	$\alpha_1, \alpha_2, \beta_1, \beta_2$	
Metaraminol	Mixed	$\alpha_1, \alpha_2, \beta_1, \beta_2$	Only α_1 effects at low dose
Mephentermine	Mixed	$\alpha_1, \alpha_2, \beta_1, \beta_2$	
Isoproterenol	Direct	β_1, β_2	
Metaproterenol	Direct	$\beta_2 > \beta_1$	β_1, β_2 equivalent when used intravenously
Aformoterol Albuterol Clenbuterol Formoterol Indacaterol Levalbuterol Oldoterol Pirbuterol Ractopamine Ritodrine Salmeterol Terbutaline Vilanterol	Direct	β_2	
Mirabergon	Direct	β_3	

intravenous, or subcutaneous administration. Iatrogenic injury or death from administration of parenteral catecholamines is a relatively common occurrence. This may occur with appropriate therapeutic dosing [1], but most typically occurs with inappropriate dosing or use. This includes improper preparation of an infusion, inappropriate infusion rate, or infusion pump malfunction. Dosing errors associated with miscalculated dose due to varying epinephrine concentrations and mg/kg dosing in pediatrics are a well-described issue [2–4]. Administration into inappropriate locations may occur as a result of injection of local anesthetic containing epinephrine into end organs, particularly digits, or similarly by release of an epinephrine autoinjector into the digit [5, 6].

Epinephrine and norepinephrine have direct α -adrenergic and β -adrenergic activity. Both are

metabolized by COMT and MAO and are not bioavailable when taken orally. Similarly, because of this efficient metabolism, they have brief durations of action.

Dopamine, a mixed acting agent, produces principally α -adrenergic and β -adrenergic effects at low parenteral doses. As the dose escalates, the α -adrenergic effects predominate. Although the clinical effects of epinephrine, norepinephrine, and dopamine are qualitatively similar, there are important differences (Table 2).

Ephedrine and Pseudoephedrine

Ephedrine was once commonly available in its herbal form, *Ephedra* or Ma Huang. In the USA, the Food and Drug Administration banned use of this dietary supplement in 2004 after numerous

reports of severe adverse events and fatalities. This led to a near resolution of these poisonings [7]. Though its commercial availability is less widespread than previously, Ephedra is still available in other countries, such as Canada, and is legal in the USA if contained in dietary supplements sold for purposes other than weight loss, such as in dietary supplements marketed for respiratory health.

The optical isomers ephedrine and pseudoephedrine are extremely similar to each other in pharmacologic properties and clinical use. Poisonings due to ephedrine or pseudoephedrine cause identical syndromes and require similar treatments. Ephedrine and pseudoephedrine are mixed-acting sympathomimetics, meaning that they have direct-and indirect-acting properties at adrenergic receptors. Similar to dopamine, they cause the release of norepinephrine. α -Adrenergic and β -adrenergic stimulation occur with ephedrine or pseudoephedrine poisoning. The half-life of ephedrine and pseudoephedrine is approximately 5 h [8, 9].

Metaraminol, Mephentermine, Methoxamine, and Midodrine

These medications are both α - and β -adrenergic agonists, but their α_1 effects are most prominent [9] and this agonism is their therapeutic purpose. Methoxamine is a relatively selective direct-acting α_1 -adrenergic receptor agonist. Metaraminol and mephentermine are mixed-acting and have direct vasoconstrictive effects but also cause release of endogenous norepinephrine. All of these agents may result in typical complications of α -adrenergic agonist poisoning, including hypertension, tachydysrhythmias or bradydysrhythmias, and CNS stimulation. Reflex bradycardia may result in response to hypertension associated with α_1 -adrenergic receptor toxicity. Metaraminol half-life is minutes long, methoxamine half-life is 3–6 h, mephentermine elimination half-life is 18 h, and midodrine half-life is 3–4 h. The extremely long half-lives relative to endogenous catecholamines have been associated with adverse outcomes when these medications have been used for cardiopulmonary resuscitation [9].

β -Adrenergic Agonists

Nonselective β -Adrenergic Agonists

Nonselective adrenergic agonists, such as isoproterenol, are typically used in the intensive care setting. Isoproterenol is a potent β_1 -receptor and β_2 -receptor agonist; causes decreased peripheral vascular resistance in skeletal muscle, renal vasculature, and mesenteric vasculature; and has a positive chronotropic and inotropic effect on the heart. As a result, isoproterenol typically causes an increase in systolic blood pressure and a decrease in diastolic blood pressure. Isoproterenol is metabolized by COMT and has a half-life of 2–5 min [9].

Selective β_2 -Agonists

The selective β_2 -agonists stimulate receptors located in bronchial, uterine, and vascular smooth muscle and are used to treat bronchoconstriction and preterm labor. Although these agents primarily stimulate β_2 -receptors, they may produce some β_1 -agonist effects, particularly at high doses.

The β_2 -agonists have nearly identical clinical effects, and the principal differences among the various agents derive from their pharmacokinetics. As such, this chapter does not examine each β_2 -agonist individually; rather, they are discussed as a class. The β_2 -agonists include albuterol, clenbuterol, formoterol, indacaterol, levalbuterol, oldoterol, pirbuterol, ritodrine, salmeterol, terbutaline, and vilanterol. The half-lives of these agents varies tremendously, with albuterol having a half-life of 4 h, but long-acting beta agonists such as albuterol, clenbuterol, formoterol, indacaterol, oldoterol, salmeterol, and vilanterol have half-lives of 20–50 h [9].

Use of β_2 -agonists is widespread, which presents several problems to the clinician treating potential toxicity. Excessive use of β_2 -agonists such as those contained in metered-dose asthma inhalers or oral preparations can result in tachyphylaxis, a phenomenon in which downregulation of receptors occurs, and the effects from this drug diminish as a result of excessive use [10]. Consequently, patients may require higher doses to achieve the same clinical effect they previously experienced at lower doses, resulting in more profound systemic side effects.

Some aspects of clenbuterol toxicity are unique and differ from other β_2 -agonists. Although clenbuterol is a selective β_2 -agonist used in human and veterinary medications as a bronchodilator, it is commonly abused by people seeking its β_3 -agonist activity, which includes anabolic and lipolytic effects.

Selective β_3 -Agonists

Mirabegron is a selective β_3 -agonist that is the only drug of its kind in this class [11]. It is a relatively new drug used to achieve relaxation of urinary bladder smooth muscle to treat symptoms of overactive bladder. The half-life is approximately 50 h.

α -Adrenergic Agonists

α -Adrenergic agents can be classified according to their relative affinity for α_1 -adrenergic or α_2 -adrenergic receptors. The primary effect of α_1 -adrenergic agonists is vasoconstriction resulting in increased peripheral vascular resistance, increased blood pressure, and often reflex bradycardia. Examples of α_1 -agonists include phenylephrine and synephrine. These medications undergo complex metabolism resulting in a duration of effect for IV doses of approximately 15 min, and by oral dosing 2–4 h.

Phenylephrine is a direct-acting α_1 -adrenergic agonist used topically as a nasal decongestant and mydriatic and intravenously as a pressor. Toxicity from topical application is described, particularly in infants and geriatric patients. Phenylephrine undergoes extensive metabolism by MAO in the intestinal wall, resulting in poor oral bioavailability. Synephrine is a plant-derived product similar in structure to phenylephrine, differing by the presence of a hydroxyl group in the para-position (synephrine) rather than the meta-position (phenylephrine or neosynephrine) on the benzene ring. Synephrine is typically present in dietary supplements derived from the herbal called bitter orange. These are often advertised with emphasis that the stimulant is “ephedra-free,” and bitter orange is now a leading sympathomimetic stimulant included in ergogenic dietary supplements since the ban on ephedra [12].

α_2 -Receptors are found in the peripheral nervous system and CNS. Peripherally, α_2 -receptors function similarly to the α_1 subtype and mediate smooth muscle contraction, causing vasoconstriction. At central adrenergic sites α_2 -adrenergic agonism result in feedback inhibition and a decreased release of catecholamines. The most prominent clinical effects include a centrally mediated reduction in blood pressure and heart rate. Common α_2 -agonists are guanabenz, guanfacine, and methyldopa; and the imidazoline agents apraclonidine, clonidine, naphazoline, oxymetazoline, tetrahydrolazine, and xylo-metazoline. Dexmedetomidine is an α_2 -adrenergic agonist with a primary effect of CNS sedation and is used specifically as a sedative or anesthetic agent. α_2 -Adrenergic agonists are discussed in detail in the ► [Chap. 35, “Alpha-2 Adrenergic and Imidazoline Receptor Agonists: Clonidine, Dexmedetomidine, and Related Antihypertensives, Decongestants, and Sedatives.”](#)

Clinical Presentation

Epinephrine, Norepinephrine, and Dopamine

The predominant clinical effects of epinephrine, norepinephrine, and dopamine are cardiovascular and include vasoconstriction and cardiac stimulation. The sequelae of poisoning with these agents include hypertension, tachycardia, dysrhythmia, acute coronary syndromes, pulmonary edema, and cerebrovascular injury [13–18]. With toxicity, patients often complain of chest pain, palpitation, headache, as well as the neuropsychiatric symptoms of anxiety, apprehension, and a sense of impending doom. Catecholamines, which generally do not cross the blood–brain barrier, produce minimal direct CNS effects [19]. The psychological and cerebrovascular effects likely are secondary to cardiovascular stimulation.

Tissue necrosis secondary to localized vasoconstriction is the potential result of end-organ administration; this most typically occurs as a result of α -adrenergic vasoconstriction, usually due to locally applied epinephrine. The

performance of “bloodless field” surgery, particularly hand and cosmetic surgery, demonstrates that epinephrine administration to digits or end organs is not an indication for mandatory antidotal therapy.

Ephedrine and Pseudoephedrine

The adverse effects of ephedrine and pseudoephedrine are the result of excessive cardiovascular stimulation by the autonomic nervous system. The expected complications of their use are qualitatively similar to the complications that occur with catecholamine use. Relative to amphetamine or methamphetamine, ephedrine and pseudoephedrine have poor CNS penetration and cause much more profound peripheral sympathomimetic effects. Patients attempting to achieve the degree of CNS stimulation produced by methamphetamine may take massive doses of ephedrine or pseudoephedrine, resulting in profound cardiovascular stimulation and its sequelae.

β -Adrenergic Agonists

Nonselective β -Adrenergic Agonists

Nonselective adrenergic agonists, such as isoproterenol, a potent β_1 -receptor and β_2 -receptor agonist, typically are used in the intensive care setting.

Selective β_2 -Agonists

The selective β_2 -agonists stimulate receptors located in bronchial, uterine, and vascular smooth muscle and are used to treat bronchoconstriction, and preterm labor. They are also used for the treatment of hyperkalemia because of their β -receptor-mediated ability to cause an intracellular influx of potassium. Although these agents primarily stimulate β_2 -receptors, they may produce some β_1 -agonist effects, particularly at high doses [20].

The β_2 -agonists have nearly identical clinical effects, and the principal differences among the various agents derive from their pharmacokinetics. As such, this chapter does not examine each β_2 -agonist individually; rather, they are discussed as a class. The β_2 -agonists include albuterol,

clenbuterol, formoterol, indacaterol, levalbuterol, oldoterol, pirbuterol, ritodrine, salmeterol, terbutaline, and vilanterol.

Use of β_2 -agonists is widespread, which presents several problems to the clinician treating potential toxicity. Excessive use of β_2 -agonists such as those contained in metered-dose asthma inhalers or oral preparations can result in tachyphylaxis, a phenomenon in which downregulation of receptors occurs, and the effects from this drug diminish as a result of excessive use [21]. Consequently, patients may require higher doses to achieve the same clinical effect they previously experienced at lower doses, resulting in more profound systemic side effects.

In the USA, clenbuterol is not approved for use in humans, and exposure to clenbuterol occurs by various manners including indicated use of clenbuterol as a bronchodilator prescribed in another country; exposure to illicitly obtained clenbuterol as an anabolic and lipolytic drug used to increase lean weight and decrease body fat; [22] use of heroin tainted with clenbuterol [23]; and consumption of beef or liver from cattle that were being clandestinely fed clenbuterol [24].

Though an illegal practice, clenbuterol is sometimes added to livestock feed to grow cattle that are more muscular and also more lean, and it is illicitly used by humans seeking the same effects of increasing muscle mass and decreasing body fat.

Adverse Effects of β -Adrenergic Agonists

The toxic effects of isoproterenol poisoning are related to its cardiostimulatory and vasodilatory properties and include tachycardia, hypotension, tachydysrhythmias, myocardial ischemia, and flushing. Commonly, CNS effects of anxiety, fear, and headache occur. Excess selective β_2 -adrenergic agonism is associated with fewer clinically significant effects than combined β_1 and β_2 agonism; this probably relates to the vasodilatory properties of the β_2 -agonists and the lack of vasoconstrictive (i.e., hypertensive) effects after their overdose.

Adverse Effects of β_2 -Adrenergic Agonists

The primary toxic effects of β_2 -agonists are cardiovascular, including hypotension, tachycardia,

and tachydysrhythmias. Elevations of creatine phosphokinase muscle (CPK-MM) and cardiac (CPK-MB) fractions as well as troponin may result after large doses of β_2 -agonists, particularly terbutaline infusions and continuous albuterol nebulization [25–27]. The clinical significance of increased CPK-MB is unclear, and it has not been shown to correlate with clinically adverse effects. Cardiac troponins may also be elevated as a result of terbutaline infusion, but the clinical significance of elevations of CPK-MB and troponin, particularly in children who most commonly receive IV β_2 -agonists, is also unclear [28, 29]. Cardiac dysrhythmia, although described with β_2 -agonist poisoning, is most frequently supraventricular in origin and clinically inconsequential. Dysrhythmias other than sinus tachycardia should not be attributed routinely to β_2 -agonist toxicity until other causes have been excluded.

Metabolic effects result from β_2 agonist toxicity but are usually of minimal consequence. Severe hypokalemia can result from β_2 -adrenergic stimulation [30]. This condition results from influx of extracellular potassium into the intracellular compartment despite normal total-body potassium content. Electrocardiographic and neuromuscular complications of hypokalemia rarely, if ever, develop. Although β_2 -agonists cause hyperglycemia, prolonged poisoning can result in hypoglycemia from depleted glucose and glycogen stores. Other effects of β_2 -adrenergic poisoning include tremor, agitation, vomiting, and hypophosphatemia [31–33].

Pediatric toxicity from β_2 -agonists, which occurs predominantly in young children treated with oral albuterol preparations, can cause significant gastrointestinal symptoms and tachycardia [27]. Nevertheless, these unintentional pediatric poisonings are extremely well tolerated in children and rarely require more than supportive treatment. For oral albuterol poisoning, 1 mg/kg seems to be the dose threshold for developing significant toxicity [34].

Clenbuterol toxicity includes cardiovascular elements expected of β_2 -agonists, most prominently palpitations and tachycardia, with β_2 -mediated hypotension. Myocardial ischemia [35] and

infarction, atypical of other β_2 -agonist poisonings, has been reported [36]. Metabolic effects of significant hypokalemia and hyperglycemia are also expected, but lactic acidemia and venous hyperoxia have been reported with clenbuterol toxicity mimicking cyanide poisoning [37]. The mechanism for this lactic acidemia is unclear. These severe effects, combined with a half-life of 24 h or greater, result in greater morbidity from clenbuterol relative to other drugs in this class.

Ritodrine, used in pregnant women for tocolysis, is associated with numerous unique toxic effects. It is unclear if these are specific to ritodrine, or if they are the result of using β_2 agonists for tocolysis, but these include agranulocytosis [38], cardiomyopathy [39], myocardial infarction [40], pulmonary edema [41], rhabdomyolysis [42], and pulmonary edema [43]. In most reported cases, these effects resolve rapidly after discontinuation of ritodrine, but standard therapies for these conditions is needed until the patient returns to baseline health.

Adverse Effects of β_3 -Adrenergic Agonists

As there is only one β_3 -agonist medication, mirabegron, that has been in use for only a few years, reports of adverse events and toxicity are very limited. The specific adverse effects are not well reported, but would be expected to be similar to β_2 -agonist toxicity. Although in theory stimulation of β_3 -receptors causes negative chronotropy, in practice medications with β_3 -agonist effects cause tachycardia as a result of its activity as β_1 and β_2 -receptors. Animal toxicity data suggests that the cardiovascular effects of mirabegron, including hypotension, tachycardia, including tachydysrhythmia and cardiac arrest may result [44]. In animal models, significant lacrimation and salivation, which are not typical of β agonist toxicity, result from high doses [45].

Adverse Effects of α_1 -Adrenergic Agonists

Direct-acting α_1 -selective agonists include phenylephrine and methoxamine, and mixed-acting α_1 -selective agonists include mephentermine,

metaraminol, and mitodrine. All of these agents are used clinically for their vasoconstrictive effects. After overdose, hypertension and reflex bradycardia typically occur. The reflex bradycardia is a homeostatic response that maintains cerebral blood flow in a physiologically acceptable range, even in the presence of a severely elevated blood pressure

Phenylephrine and Sympheprine

Though described independently, it is likely that complications resulting from either of these agents are possible with both drugs. Complications described with phenylephrine include psychosis, seizure, hypertension, myocardial infarction [46], and intracerebral hemorrhage [47, 48].

The most significant adverse effects of syneprine are cardiovascular, and include palpitations, tachycardia, tachydysrhythmia, myocardial infarction [49, 50], cardiac arrest, and stroke. Ischemic colitis [51] and rhabdomyolysis [52] have also been described in association with syneprine use.

Methoxamine, Metaraminol, and Mitodrine

All of these agents may result in typical complications of α -adrenergic agonist poisoning, including hypertension, tachydysrhythmias or bradydysrhythmias, and CNS stimulation. Reflex bradycardia may result in response to hypertension associated with α_1 -adrenergic receptor toxicity.

Diagnosis

Sympathomimetic overdose is a clinical diagnosis. Some laboratory findings, such as hypokalemia and hyperglycemia, may be present, but they play little role in diagnosis. Although sympathomimetic drugs and the endogenous catecholamines can be selectively assayed, the results typically are not available in a clinically relevant period of time. Urine drug screens, which can detect the structurally similar amphetamine derivatives by immunoassay, are neither

Table 3 Differential diagnosis of sympathomimetic syndrome

Anticholinergic syndrome

Withdrawal syndromes

sufficiently sensitive nor sufficiently specific to be clinically useful during the acute management of sympathomimetic drug toxicity. The differential diagnosis of sympathomimetic poisoning is listed in Table 3.

Treatment

The mainstay of therapy for adrenoceptor overstimulation is correction and maintenance of vital signs to within acceptable limits. For agents that produce predominantly psychomotor agitation and increased autonomic activity, sedation and control of symptoms such as vomiting are generally sufficient.

Patients poisoned by peripherally acting agents occasionally require the judicious use of specific α or β antagonists but most commonly need nonspecific medications such as antiemetics, benzodiazepines, or nonadrenergic antihypertensives such as hydralazine or calcium channel blockers (Evidence: Level I) (Table 4).

These therapies should not be initiated prematurely or indiscriminately because inappropriate use of these antagonists can result in unpredictable adverse effects. In a patient with a nonspecific adrenergic agonist overdose, such as ephedrine poisoning, the unopposed α -adrenergic stimulation that remains after β -adrenergic blockade may

Table 4 Drugs used in treatment of sympathomimetic toxicity

Drug	Indication	Action	Dose
Hydralazine	Hypertension	Vasodilation	0.1–0.5 mg/kg/dose (up to 20 mg)
Nicardipine	Hypertension	Vasodilation	0.5–1 mcg/kg/min IV titrated up to 5 mcg/kg/min
Nitroprusside	Hypertension	Vasodilation	0.3–10 µg/kg/min IV, titrated to effect
Phentolamine	Hypertension	α antagonism	Child: 0.1 mg/kg/dose (up to 5 mg/dose) IV repeated every 10 min PRN Adult: 5 mg IV repeated every 5 min PRN
	Extravasation of catecholamine	α antagonism	5–10 mg in 10 mL of normal saline infiltrated SC in appropriate quantity
Terbutaline	Extravasation of catecholamine	β ₂ agonism	Child: 0.01 mg/kg/dose SC every 15 min to maximum of 0.4 mg/2 h ^a Adult: 0.1 mg SC every 15 min to maximum of 0.4 mg/2 h ^a
Esmolol	Hypertension	β antagonism	500 µg/kg/min IV bolus followed by infusion 50 µg/kg/min titrated to effect up to 500 µg/kg/min
Metoprolol	Hypertension	β antagonism	Child: Pediatric dose not established Adult: 2.5–5 mg IV every 5 min to a maximum of 15 mg
Propranolol	Hypertension	β antagonism	Child: 0.05–0.1 mg/kg slow IV (up to 1 mg/dose), repeated every 15 min to maximum of 5 mg total dose Adult: 0.5–1 mg slow IV, repeated every 15 min to maximum of 5 mg total dose
Labetalol	Hypertension	β antagonism, some α antagonism	Child: 0.2–0.5 mg/kg/dose IV, maximal dose 20 mg, followed by infusion of 0.25–1 mg/kg/h Adult: 20 mg slow IV, may repeated every 10 min PRN or 2 mg/kg/min infusion titrated to effect

IV intravenously, PRN as needed, SC subcutaneously

^aThese doses are based on 1 mg/mL solution

be associated with acute deterioration of the patient's vital signs [53].

Indications for ICU Admission in Sympathomimetic Agent Poisoning

- Manifestations of vital end-organ injury (e.g., myocardial ischemia or infarction, cerebrovascular accident, cerebral hemorrhage, liver function abnormality)
- Cardiac dysrhythmias other than sinus tachycardia
- Hypokalemia requiring cardiac monitoring or potassium supplementation
- Cardiovascular effects requiring ongoing therapy with cardiovascular agents (e.g., nitroprusside infusion)
- Ongoing morbidity requiring monitoring and treatment (e.g., hyperthermia, rhabdomyolysis, or renal insufficiency)

Treatment of Toxicity from Combined α-Adrenergic and β-Adrenergic Agents

Because of the short duration of action of epinephrine, norepinephrine, and dopamine, the treatment of systemic toxicity, beyond supportive care, is typically unnecessary, unless complications arise (Evidence: Level III). Discontinuation of the infused or administered drug is followed by fairly prompt cessation of signs and symptoms.

Treatment of systemic toxicity resulting from longer acting sympathomimetic agents should focus on correcting the vital sign abnormalities to within acceptable limits, including aggressive management of hyperthermia and control of neurobehavioral effects. Vasoconstrictive effects may be managed safely with phentolamine, hydralazine, a dihydropyridine calcium channel blocker, or sodium nitroprusside, but the

chronotropic and inotropic effects are abated only by the administration of diltiazem, verapamil, or a β -adrenergic antagonist. β -Adrenergic antagonists are not advised routinely, however, unless a vasorelaxant agent is coadministered (Evidence: Level III). The concern over the use of a β -blocker in such a situation is that it may result in unopposed α -adrenergic activity and hypertension. The danger of administering a β -blocker in the presence of an agent with combined α -adrenergic and β -adrenergic activity may be overstated, and β -blockers have been administered successfully in these situations [54]. At this time, if patients are manifesting sympathomimetic signs, we do not recommend routine use of a β -blocker to treat patients exposed to adrenergic agonists, such as cocaine, amphetamines, or ephedrine unless a second antihypertensive with vasodilatory effects, such as an alpha blocker or calcium channel blocker, is coadministered (Evidence: Level III).

Psychomotor agitation can be treated with benzodiazepines, such as lorazepam or diazepam (Evidence: Level III). Attempts at gastrointestinal decontamination of these patients with activated charcoal has not been shown to affect their outcome. If the patient is capable of drinking the AC without the need for a nasogastric tube, has not vomited, and is at risk for an adverse outcome due to the poisoning, then a single dose of AC is indicated for most patients.

Although there are not sufficient published data to make broad-based recommendations about treatment for digital administration of epinephrine, it is generally accepted that in the absence of comorbidities, such as diabetic vasculopathy, pallor in a digit or end organ lasting only a few hours is usually safe (Evidence: Level II-2). If deemed necessary, such as for severe ischemic pain, treatment for end-organ epinephrine administration is directed at increasing blood flow to the affected area; this can be accomplished by warming the area or by vasodilation achieved by application of topical nitroglycerin paste. Alternatively phentolamine may be injected into the affected area, directly into the initial puncture wound if possible, to antagonize epinephrine's α_1 -adrenergic vasoconstrictive

effect [55]. Many clinicians have limited experience with phentolamine, and because this agent is not used frequently it may be difficult to obtain. Injection of terbutaline into the affected tissues may also produce local vasodilation. In cases of inadvertent digital administration of epinephrine, terbutaline can be injected into the site of pallor in a manner similar to that described above [56]. Terbutaline offers the advantage of being much more readily available and better known to clinicians, though use for this indication has limited evidence supporting it [57, 58]. Terbutaline typically is available in a concentration of 1 mg/mL. In our experience in adults, an intravenous injection of 0.1 mg is an appropriate initial dose; this dose can be repeated in 15 min if necessary. If the epinephrine injection occurred in an area of loose flesh such as the thenar eminence or pad of the distal phalanx, the dose of terbutaline can be diluted in 0.3–0.5 mL of normal saline to allow greater tissue distribution. Terbutaline may cause tachycardia is not recommended for patients at risk for myocardial ischemia.

Treatment of β -Adrenergic Agonist Poisoning

Supportive care is the mainstay of treatment. Most patients with β -adrenergic agonist-mediated hypotension and tachycardia respond to intravascular volume expansion with intravenous saline. In our experience, administration of vasopressors generally is unnecessary but may be required in patients with refractory, symptomatic, and vasodilatory hypotension.

Conceptually the use of a β -blocker is an ideal therapy for hypotensive patients following β -adrenergic agonist poisoning. Although use of a β -blocker to treat hypotension may seem counterintuitive, reversal of the β_2 -mediated vasodilation is expected to raise the blood pressure (Evidence: Level II-2). This use should be approached cautiously however, and generally only after other therapies have failed, particularly because there are currently no short-acting selective β_2 -blockers. Patients with hemodynamically

consequential tachydysrhythmias may be treated with β -blockers. In this situation, it is prudent to use a short-acting agent, such as esmolol. Although they are typically contraindicated in asthmatic patients, there is evidence that the judicious use of short-acting β -blockers such as esmolol may be acceptable [59].

Treatment of clinically significant hypokalemia consists of cautious small boluses of potassium (Evidence: Level III). This use must be distinguished from the higher doses used in total-body potassium repletion however, because efflux of potassium from the extracellular compartment follows resolution of the β_2 -agonist effect. Aggressive administration of potassium during the period of symptomatic hypokalemia potentially can result in hyperkalemia.

Treatment of α -Adrenergic Agonist Toxicity

General principles of normalization of vital signs within acceptable limits should be employed. The considerations regarding attempts at gastrointestinal decontamination are the same as those described above for β agonist poisoning. Further, many agents are concentrated liquid preparations used parenterally, topically on mucous membranes, or as inhalational agents, so the ability to perform gastrointestinal decontamination may be limited.

Treatment of hypertension should be administered based solely on measured, not anticipative, elevations in blood pressure. This recommendation is particularly important in healthy patients whose normal blood pressures are far lower than the blood pressures used to define hypertensive urgency or emergency (Evidence: Level II-2).

Hypertension resulting from α_1 -adrenergic stimulation can be treated most specifically with phentolamine, an α_1 -adrenergic antagonist. Less specific but still effective therapy more familiar to most clinicians includes direct-acting vasodilators, such as hydralazine, nitroprusside, nitroglycerin, or the dihydropyridine class of calcium channel blockers such as nicardipine or fenoldopam. In our experience, the treatment of

reflex bradycardia is rarely necessary and should resolve with improvement in the patient's blood pressure.

Special Situations

Several unique issues relevant to sympathomimetic toxicity warrant mention. Monoamine oxidase inhibitor use can result in exaggerated pressor response to indirect-acting sympathomimetics because of increased presynaptic stores of catecholamines. The concomitant use of inhalational or halogenated anesthetics can sensitize the myocardium to β -adrenergic agonism, resulting in dysrhythmia on release of endogenous or exposure to exogenous catecholamines. Patients requiring pressors after poisoning by catecholamine reuptake inhibitors, such as tricyclic antidepressants, may not respond to the administration of dopamine or other indirect-acting pressors. These patients may respond, however, to a direct-acting adrenergic agonist. Similarly, patients with catecholamine depletion, such as patients who have been using large amounts of a sympathomimetic agent, may not respond to indirect-acting agents but do respond to direct-acting agents.

By the turn of the twentieth century, interest in allergic response and particularly the phenomenon of anaphylaxis had become intense. In 1902, Portier and Richet provided further focus for the study by developing the concept of altered animal reactivity, which they termed *allergy* [1]. Of the biologic amines released in the inflammatory process, histamine was the first described, originally termed β -aminoethylimidazole. Histamine's actions on the gut, bronchioles, and heart were reported in 1910 [2, 3]. The work on the receptor theory of drug action was well under way when the first articles on anaphylaxis were published. It was not until 1933, however, when Clark published *The Mode of Action of Drugs on Cells* [4], that acceptance of that theory became sufficient to stimulate a search for compounds that might block histamine's effects. Many compounds with antihistaminic activity were produced, but their toxicity precluded use in humans. In 1941, a French patent was obtained for N₁N-dimethyl-N₁-benzyl-N-phenylethylenediamine, the first antihistamine in human clinical use. Diphenhydramine followed in 1945. The designation *H₁ receptors* was proposed in 1966 [5], and by 1972, the existence of H₂ receptors had been confirmed [6]. Subsequently, use of H₁ and H₂ antagonists became widespread. Nonsedating second-generation antihistamines were developed in the 1980s when their inability to penetrate the central nervous system (CNS) was exploited. Adverse effects, particularly the occasional occurrence of torsades de pointes, were noted in the late 1980s. Emanuel [7] provides a

detailed history of the understanding and development of antihistamines.

Biochemistry and Clinical Pharmacology

Kinetics for Oral Exposure in Healthy Adults

See Table 1.

Antihistamines are classified based on their affinities for either H_1 or H_2 receptors. Antihistamines classified as H_1 -receptor antagonists are divided further into first-generation agents (less H_1 receptor specificity and high blood–brain barrier penetration) and second-generation agents (more H_1 receptor specificity and low blood–brain barrier penetration) (Figs. 1 and 2) [8].

Pathophysiology of Toxic Effects

The therapeutic effects of antihistamines are related to their ability to bind to and block histaminic receptors throughout the body (Fig. 3). The therapeutic effects of H_1 -receptor antagonists result from the blockade of receptors in the vasculature, bronchioles, cardiac tissues, and sensory nerves as well as prevention of release of further histamine from mast cells and basophils [9]. Clinically, this activity results in decreasing the systemic effects of allergic reactions. H_2 -receptor antagonists derive their benefit from inhibiting gastric acid secretion and subsequently treating and preventing gastric and duodenal ulcers. The toxic effects of antihistamines occur when either histaminic receptors in the CNS or non-histaminic receptors in the CNS and peripheral nervous system are antagonized.

In the CNS, there are four classes of histamine receptors: H_1 , H_2 , H_3 , and H_4 receptors [10, 11]. H_1 receptors are thought to have a modulatory role in the CNS, affecting numerous functions, including sleep–wake cycles, thirst, thermoregulation, and prevention of seizures [12, 13]. Antagonism of central H_1 receptors can result in somnolence [14] and seizures [15].

Table 1 Pharmacokinetics of oral exposures to commonly used antihistamines in healthy adults

Compound	Peak effect (h)	Half-life (h)
H_1 blockers		
Brompheniramine	3–9	12–34
Cetirizine	1–2	6.5–10
Chlorpheniramine	2	12–43
Cyproheptadine pharmacokinetics: cyproheptadine	6–9	8–9
Dexchlorpheniramine	3	3–6 (duration)
Dimenhydrinate	0.25–0.5 (onset)	3–9.3
Diphenhydramine	1–3	2–8
Doxylamine	1–4	7–13
Hydroxyzine	0.25–0.5 (onset)	3–6 (duration)
Loratadine	8–12	12–15
Meclizine	1 (onset)	8–24 (duration)
Promethazine	0.3 (onset)	2–6 (duration)
Tripeleennamine	0.25–0.5 (onset)	2–8 (duration)
H_2 blockers		
Cimetidine	1–2	2–4
Famotidine	1 (onset)	10–12 (duration)
Nizatidine	0.5–3	1.3
Ranitidine hydrochloride	1–3	2.5

The mechanism of sedation is believed to be the inhibition of central H_1 receptors [16]. In cultured human cortical neurons, histamine blocks the background leakage of potassium, resulting in neuronal membrane depolarization and consequent generation of action potentials. This blockade, along with histamine's distribution in the CNS, is the basis of histamine's presumed role in arousal. The blockade of background potassium currents can be inhibited by selective H_1 -receptor

Fig. 1 Chemical structures of first-generation antihistamines (sedating)

(but not H_2) antagonists, resulting in decreased neuronal firing and CNS depression [14]. Traditionally, antihistamine-induced seizures were thought to be due to either their local anesthetic effects or their anticholinergic effects. Antihistamines' ability to cause seizures does not correlate, however, with their affinity for muscarinic

receptors and is not reversed by physostigmine [15, 17]. Laboratory studies in mice and rats using histidine, a histamine precursor, and blockers of histamine metabolism have shown significant decreases in the incidence of experimentally induced seizures, suggesting that histamine may play a role in the CNS in seizure

Fig. 2 Chemical structures of second-generation antihistamines (nonsedating)

prevention. Administration of H_1 antagonists lowers the seizure threshold, resulting in epileptic activity [12, 18–21]. The role of central H_2 receptors is not well known, but when animals are given large doses of H_2 blockers, seizures may occur [22]. The presynaptic H_3 receptor works as an autoreceptor regulating the release and

synthesis of histamine. Although experimental H_3 -receptor antagonists are being investigated as possible anticonvulsants [23], no clinically relevant agents currently are available.

In part as a result of the similarity in amino acid sequences between H_1 and muscarinic receptors [24], first-generation H_1 antagonists cause CNS

Fig. 3 Schematic model of a central histaminergic neuron. Histidine crosses the blood–brain barrier and, when inside neurons, is converted to histamine (*H*) via the enzyme histidine decarboxylase. *H* is transported into vesicles, where it is stored before release. Free *H* can be metabolized by histamine methyltransferase with methylhistamine and then metabolized further through the monoamine oxidase (*MAO*) system. *H* binding to *H*₁ receptors stimulates phospholipase C (*PLP C*) with the liberation of inositol triphosphate (*IP*₃) and diacylglycerol (*DAG*) as second messengers. *H* binding to *H*₂ receptors stimulates adenylate cyclase with the generation of cyclic adenosine monophosphate (*cAMP*) as a second messenger. *H* binding to *H*₃ autoreceptors results in feedback inhibition and decreases release of *H* and numerous other neurotransmitters. *ATP* adenosine triphosphate, *G* G protein

and peripheral nervous system anticholinergic effects. Some adverse effects of antihistamines are related to complications of overdosage (aspiration pneumonia, anoxia, and rhabdomyolysis) or are idiosyncratic (dystonia, thrombocytopenia, and leukopenia).

The cardiac effects of antihistamines include effects resulting from sodium channel blockade (e.g., ventricular dysrhythmias) and potassium efflux blockade (e.g., torsades de pointes). Serious cardiac effects of first-generation (sedating)

antihistamines generally are thought to be secondary to sodium channel blockade. Numerous reports of diphenhydramine toxicity have shown QRS widening and hypotension. Some of these patients showed resolution of these effects after receiving doses of physostigmine and sodium bicarbonate [25, 26], whereas others responded to sodium bicarbonate alone, supporting the theory that sodium channel blockade was a major factor. Wang and colleagues [27] studied the effects of “conventional” antihistamines on cardiac conduction and found that cardiac repolarization was slowed in the following order: clemastine, hydroxyzine > brompheniramine, chlorpheniramine, diphenhydramine > cyproheptadine, chlorcyclizine, promethazine. They also showed the dose-dependent ability of these drugs to prolong the QT interval. The authors suggested that large doses of these medications might have adverse effects on cardiac conduction. Zareba and associates [28] reviewed 12-lead electrocardiograms of 126 consecutive patients with diphenhydramine overdoses reported to regional poison centers. Of patients, 25% had heart rates greater than 120 beats/min, probably owing to the anticholinergic effects of diphenhydramine. QT_c prolongation was common, with 50% of the patients having a QT_c interval of greater than 450 ms and 11% greater than 500 ms. Only one patient presented with monomorphic ventricular tachycardia, and no patients had torsades de pointes.

Second-generation antihistamines, such as astemizole, terfenadine, and ebastine, seem to cause torsades de pointes by inhibiting potassium efflux from cells in the cardiac conduction system. The blockade of the “delayed rectifier” potassium current in late phase 2 and early phase 3 of the action potential seems to be responsible for prolongation of the QT interval and a contributor to the development of torsades de pointes (Fig. 4) [29].

Blockade of potassium channels leads to an increase in membrane potential (i.e., toward zero) and allows Purkinje fibers to “refire.” This event is termed an *afterdepolarization* because it must follow a normal cellular depolarization and cannot arise de novo. When an afterdepolarization occurs

Fig. 4 The relationship between the action potential and the QRS. Although changes in sodium influx during phase 0 leads to QRS prolongation, blockade of potassium channels in phase 2 and phase 3 lengthens the QT interval

in late phase 2 or early phase 3, it is termed an *early afterdepolarization* (EAD). These early afterdepolarizations initiate “triggered” activity, such as torsades de pointes (Fig. 5) [30]. Terfenadine and astemizole have been removed from the market in most countries due to this effect. Fexofenadine, a metabolite of terfenadine without significant potassium channel-blocking properties, has largely replaced them.

Clinical Presentation and Life-Threatening Effects

Neurologic Effects

Diphenhydramine and the older first-generation H_1 -receptor antagonists commonly are used in over-the-counter sleep preparations, and one of the most common manifestations of H_1 -receptor antagonist overdose is sedation. At therapeutic doses, H_1 -receptor antagonists have been shown to decrease time to sleep, psychomotor function, and cognitive function [16, 31]. In a well-designed simulated driving performance test, drivers who ingested 50 mg of diphenhydramine performed similarly to, and in some scenarios worse than, drivers ingesting ethanol (blood ethanol concentration 0.1%) [32]. As a result of

Fig. 5 The production of early afterdepolarization (EAD) and torsades de pointes. The retention of potassium ions within Purkinje cells leads to a refring of the cell and the production of an EAD. This can lead to the onset of torsades de pointes, which is heralded by a slowing of the rate and a prominent U wave. T T wave

diminished CNS penetration, second-generation H_1 antagonists have a lower incidence of sedation [31]. In overdose, patients can present with a spectrum of CNS depression ranging from mild sedation to coma.

Antihistamines’ association with seizures has been known since shortly after their initial clinical usage [33]. Focal and generalized seizures in overdoses, supratherapeutic doses, and therapeutic doses were reported [33–35]. In a 2-year retrospective poison center review of 191 cases of poisoning associated with seizure, Olson and colleagues [36] showed diphenhydramine to be the third leading cause. In fatal overdoses involving antihistamines, seizures often are premonitory to cardiac arrhythmias and death [37–39]. According to a study from the ToxIC database in 2013, over-the-counter anticholinergics/antihistamines were the second leading cause of drug-induced pediatric seizures [40]. All first-generation H_1 -receptor antagonists have the potential to cause anticholinergic syndrome. There are many examples in the literature of anticholinergic poisoning with peripheral nervous system signs (dry mouth, dry skin, decreased bowel sounds, urinary retention,

mydriasis, and tachycardia) and CNS anticholinergic signs (altered mental status, confusion, psychosis) in antihistamine overdoses. For further discussion on the presentation and treatment of anticholinergic poisonings, see ► Chap. 23, “Anticholinergic Syndrome.”

Diphenhydramine often is used as a first-line treatment for extrapyramidal effects secondary to dopamine antagonists. Its mechanism of reversal may occur through either its central antimuscarinic effects [41] or its ability to inhibit dopamine uptake in neuronal cells [42–44]. Despite this, antihistamines also have been reported to be a cause of extrapyramidal symptoms. Cases of orofacial dyskinesias, acute dystonia, torticollis, trismus, tremors, and incoordination have been reported in patients with acute and long-term usage of antihistamines in therapeutic doses and overdoses [45–54]. Patients who develop antihistamine-associated extrapyramidal effects should be treated with either benzodiazepines or benztropine, a relatively potent inhibitor of central dopamine uptake (see ► Chap. 44, “Antipsychotics”).

Cardiac Effects

Tachycardia due to anticholinergic effects is the most common cardiac presentation [55] and seldom requires treatment. Wide QRS and ventricular tachycardia have been reported and may be treated with sodium bicarbonate in a fashion similar to that caused by tricyclic antidepressants (LOE III) [56]. Prolonged QT_c and torsades de pointes also have been reported, especially with nonsedating agents, such as terfenadine and astemizole. Hypertension and hypotension have been documented [57].

Nonsedating second-generation H₁ antagonists were introduced in the 1980s. In 1986, Craft [58] reported torsades de pointes in a 16-year-old who ingested an overdose of astemizole. By 1990, reports of an association between second-generation antihistamines (terfenadine, ebastine, and astemizole and its metabolite desmethylassemizole) [59] and torsades de pointes began to appear in the medical literature [60, 61]. In 1988,

Snook and colleagues [62] reported torsades de pointes associated with astemizole use. Monahan and coworkers [63] reported 25 cases of terfenadine toxicity resulting in torsades de pointes. The cardiac effects of these drugs seem to be independent of their antihistaminic properties and better associated with substitutions at the nitrogen atom (see Fig. 2) [64].

Other Effects

Rhabdomyolysis in uncomplicated antihistamine overdose is a rare event without complicating factors. Diphenhydramine and doxylamine exposures have been the most commonly reported [65–70]. As with other serious intoxications, however, antihistamine overdose can result in rhabdomyolysis. Severe cases of rhabdomyolysis typically are associated with seizures and hyperthermia [71–73]. Other features of antihistamine overdose that may contribute to the development of rhabdomyolysis include prolonged periods of inactivity with the development of compartment syndromes and agitation in patients fighting against restraints. A thorough discussion of drug-induced rhabdomyolysis is provided in the chapter devoted to that topic.

Therapeutic use of H₂ antagonists has been associated idiosyncratically (i.e., in a non-dose-related fashion) with thrombocytopenia and granulocytopenia. Numerous case reports have been published of thrombocytopenia isolated [74–86] or in combination with anemia or leukopenia or both [87–94]. The data behind most of these case reports are confounded by complicating factors and other medications not taken into account. In a systematic review of published case reports of drug-induced thrombocytopenia, only cimetidine had data considered level I evidence (definite), and ranitidine had level II evidence (probable) [95]. The cause of thrombocytopenia with H₂ antagonists generally is thought to be immune mediated with the development of IgE [75, 95, 96] or IgG and IgM antibodies [75, 76, 84] against an H₂ antagonist–platelet complex. Although some authors have suggested cross-reactivity between different H₂ antagonists [76,

96], others have shown no recurrence of thrombocytopenia when a different H₂ antagonist was used [83, 97]. Similarly, numerous case reports of granulocytopenia have been associated with therapeutic administration of cimetidine [87–91, 94, 98–101] and famotidine [92]. In most of these cases, patients either were critically ill or were using other medications with suspected bone marrow toxicity. The causes of leukopenia have been thought to be either H₂ blockade on bone marrow cells [102] or peripheral destruction of leukocytes secondary to antibodies to cimetidine [91].

Diagnosis

There are no specific laboratory or physical examination findings that indicate a diagnosis of antihistamine poisoning. Rather, a combination of CNS depression, anticholinergic findings, and electrocardiogram findings would put antihistamines on the list of differential diagnoses. Anticholinergic findings typically predominate. More important is the ability of the critical care physician or medical toxicologist to recognize and treat the features of antihistamine overdoses that are potentially life-threatening, including a loss of airway protection, widened QRS, ventricular tachycardia, prolonged QT_c, torsades de pointes, rhabdomyolysis, or seizures. Interestingly, urine drug screen testing using immunoassay kits has been reported to give false-positive methadone and phencyclidine (PCP) tests with doxylamine toxicity [103]. In addition, diphenhydramine has been reported to cause false-positive results for PCP, methadone, and tricyclic antidepressants [104–107]. Brompheniramine and ranitidine have been shown to result in false-positives for amphetamines [104].

Treatment

Treatment of antihistamine poisoning focuses on the prevention and treatment of life-threatening complications. Although antihistamines are effectively bound to charcoal, there are no specific decontamination recommendations for

antihistamines because none have been validated empirically. A further discussion of the issue of activated charcoal can be found ► [Chap. 10, “The Critically Poisoned Worker.”](#)

Secondary to the relatively high volume of distribution and protein binding of most antihistamines, extracorporeal removal is not effective in antihistamine poisoning. However, the use of hemodialysis has been reported for diphenhydramine toxicity in a child with wide complex tachycardia and persistent seizures who ultimately survived without sequelae [108]. Given that hemodialysis is unlikely to remove pharmacologically significant quantities of diphenhydramine, it is unlikely that this intervention contributed to the child’s recovery.

The management of CNS sedation with H₁-receptor antagonists rests largely on supportive care, including airway management if indicated clinically. The anticholinergic effects of antihistamines can be reversed with physostigmine (LOE II-3) [109, 110]. Because of the remote risk of seizures and arrhythmias, the empirical use of physostigmine should be reserved for patients with major anticholinergic manifestations (see ► [Chaps. 23, “Anticholinergic Syndrome,”](#) and ► [161, “Physostigmine”](#)) [111–113]. It should be recognized that physostigmine is contraindicated in the presence of seizures and/or ventricular tachycardia. It should be used with caution in patients with significant QRS prolongation. Use of dexmedetomidine as an adjunctive therapy for anticholinergic toxidrome from diphenhydramine has been recently described. The authors suggest that adding this agent may help relieve symptoms of agitation, psychosis, and tachycardia, while decreasing the risk of respiratory depression that can develop with high-dose benzodiazepines (LOE III) [114].

Benzodiazepines (e.g., diazepam and lorazepam) should be considered the first-line treatment for seizures associated with antihistamine overdosage (LOE III), followed by barbiturates (e.g., phenobarbital and pentobarbital) (LOE III) or propofol (LOE III) (see ► [Chap. 20, “Toxicant-Induced Seizures”](#) for a more detailed account of seizure management. Phenytoin is not recommended in most cases of toxin-induced

Table 2 Level of evidence regarding indications for ICU admission in antihistamine poisoning

	Evidence level
Central nervous system depression or coma	III
Seizures	III
Anticholinergic delirium	III
New-onset QRS widening beyond 110 ms	III
New-onset QT _c interval prolongation	III
Ventricular tachycardia	III
Hypotension	III
Airway compromise, hypoventilation	III

seizures because numerous animal studies have suggested that it is inferior to benzodiazepines or barbiturates and, in some overdoses, may lower the seizure threshold [115].

Indications for ICU Admission in Antihistamine Toxicity

See Table 2.

Tachycardia associated with anticholinergic effects seldom requires treatment. Prolonged QRS or ventricular tachycardia may respond to boluses of sodium bicarbonate (LOE III) [56]. Bicarbonate dosing is variable, typically with a starting point of 1–2 mEq/kg. Sodium bicarbonate infusions of 100–150 mL in 1000 mL of 5% dextrose in water (with potassium chloride added) often have been used after conversion of ventricular tachycardia, although the scientific basis for this practice is marginal (see ► Chap. 39, “Sodium Channel-Blocking Antidysrhythmics”). Lidocaine is a second-line drug for ventricular tachycardia (LOE III), and magnesium sulfate has also been used successfully (LOE I) [15, 116, 117]. The role of amiodarone is less clear, and concerns of the development of torsades de pointes have been raised [118] because of its tendency to prolong the QT_c. However, amiodarone-induced torsade is rare. Recently, intravenous lipid emulsion (ILE) therapy has also been reported as a possible

treatment option in cases of diphenhydramine-induced ventricular tachycardia not responding to treatment with sodium bicarbonate (LOE III) [119–121]. However, certain potential complications must be kept in mind concerning ILE therapy including laboratory interference, pancreatitis, and possibly acute respiratory distress syndrome [122]. The clinical pharmacology of intravenous lipid emulsion therapy is discussed in the chapter devoted to it in the “Antidotes” section. Intravenous magnesium sulfate may be effective in the treatment of torsades de pointes (LOE III). Although there are no clear guidelines for magnesium sulfate dosage, adults may be treated with 2 g (16 mEq) mixed in 50–100 mL of 5% dextrose in water intravenously over 5 min (faster if the patient is unstable) and repeated if no improvement is noted; infusion of 3–50 mg/min also may be administered. Other treatment modalities for torsades de pointes include intravenous administration of isoproterenol and use of electrical cardiac pacing (LOE III). Both modalities have had some success in torsades de pointes treatment. Isoproterenol (LOE III) may be used in patients who are bradycardic [123, 124] but should be avoided in patients with poor left ventricular function or severe coronary artery disease. Other drugs that have been used include verapamil [125, 126] and drugs that facilitate potassium channel opening, such as pinacidil [127, 128]; however, their roles in treatment remain to be determined. Further detail can be found in ► Chap. 21, “Cardiac Conduction and Rate Disturbances.” Finally, if readily available therapeutic interventions fail to terminate life-threatening dysrhythmias, extracorporeal membrane oxygenation should be considered [129, 130] (LOE II-3).

Special Populations

Pediatric Patients

In one reported case series of antihistamine poisonings, it was suggested that children are more prone to seizures than adults [34]. This association has not been validated prospectively. Antihistamines are used widely in children and carry risks

similar to those in adults. Patients with long QT syndrome due to congenital alteration in cardiac ion channels (Jervell and Lange-Nielsen and Romano-Ward syndromes) may be at increased risk for drug-induced torsades de pointes.

Female Patients

Women seem to be at a greater risk of developing torsades de pointes because of genetic differences in the number of potassium channels [131]. In a review of 332 cases of torsades de pointes, Makkar and associates [132] found a female predominance among all of the drug-induced cases except procainamide.

Elderly Patients

Elderly patients may be more prone to develop altered mental status in association with H₁- and H₂-receptor antagonists. A prospective cohort study showed that patients older than 70 years of age who received a dose of antihistamines during hospitalization had a relative risk of 1.7 for delirium [133]. Other articles have suggested a similar trend with H₂ antagonists in the elderly, particularly if concomitant renal impairment is present [134].

Patients Taking Other Medications

As a result of its ability to inhibit cytochromes 1A2, 2C18, 2D6, and 3A4, cimetidine can increase serum concentrations of numerous drugs, including theophylline, opioids, antihypertensives, antibiotics, and antidepressants. H₂ antagonists can reduce the bioavailability and effectiveness of the antifungal medications ketoconazole and itraconazole because these medications require an acidic medium in the gut for absorption.

Coingestion of cytochrome 3A4 inhibitors, such as ketoconazole, itraconazole, cyclosporine, erythromycin, nifedipine, verapamil, and grapefruit juice, may lead to a buildup of the cardiotoxic

second-generation antihistamine (i.e., terfenadine and astemizole) parent compounds, which can induce torsades de pointes. Terfenadine and astemizole have been removed from the market in many countries.

Pregnant Patients

US Food and Drug Administration safety ratings for use in pregnancy vary with specific agents, but antihistamines often are rated category C (risks in animal but not in human studies; benefits may outweigh risks). In a meta-analysis of 24 articles involving 200,000 enrolled participants, Seto and colleagues [135] concluded: "H₁ blockers used mainly for morning sickness during the first trimester do not increase the teratogenic risk in humans and may, in fact, be associated with a protective effect."

Key Points

1. Must recognize and treat the potentially life-threatening complications of antihistamine overdoses, including loss of airway protection, widened QRS, ventricular tachycardia, prolonged QT_c, torsades de pointes, rhabdomyolysis, and seizures.
2. Common cause of drug-induced pediatric seizures, second only to antidepressants.
3. Although a common presentation, sinus tachycardia seldom requires treatment.
4. Benzodiazepines should be considered the first-line treatment for seizures.

Key Points in the Evaluation and Management of Methylxanthine Poisoning

1. In acute intoxication, serum concentration is the most important prognostic indicator of life-threatening events.
2. In chronic intoxication, age is the most important prognostic indicator of life-threatening events.
3. Extracorporeal drug removal should be considered in any patient who is at high risk for a life-threatening event. When a life-threatening event occurs, there may be significant morbidity and mortality despite extracorporeal drug removal.

The methylxanthines are a group of pharmaceuticals that antagonize adenosine receptors in the central nervous system and peripheral tissues. Pharmaceutically active methylxanthines include caffeine, theophylline, and pentoxifylline. A fourth methylxanthine, theobromine, is present in cocoa products, but is not used as a pharmaceutical, and has toxicological importance in nonhuman animal species. Severe intoxication with methylxanthines may result in life-threatening arrhythmias and seizures and has a historic mortality of up to 10% [1–4].

Differential substitution on the core xanthine structure confers varying properties and organ effects on the methylxanthines (Fig. 1). For example, the presence of a methyl group at the three

position of theophylline confers its bronchodilatory properties and is preferentially used in bronchospastic diseases.

Theophylline is used for its bronchodilator properties in chronic obstructive pulmonary disease and asthma and in neonates for apnea and bradycardia of prematurity. It is used less frequently today because new pharmacologic agents have been introduced to treat these diseases and because of concerns about its narrow therapeutic index. Oral forms of theophylline are available as either immediate-release or sustained-release preparations. Sustained-release preparations have been prescribed more frequently. Theophylline is absorbed completely after oral therapeutic doses. Theophylline intoxications have been classified as acute intentional, chronic unintentional intoxication, and acute on chronic intentional. Aminophylline is an ethylenediamine salt of theophylline that has greater water solubility and is used intravenously for the same indications. It may be used off-label as a reversal agent for pharmacologic cardiac stress testing.

Caffeine is the most commonly used psychoactive substance worldwide [5] and is contained

in beverages such as coffee, tea, cola drinks, and energy drinks. As a pharmaceutical, caffeine is used in combination with headache remedies (e.g., acetaminophen/aspirin/caffeine/+/–diphenhydramine, butalbital/acetaminophen/caffeine, butalbital/aspirin/caffeine) and for apnea of prematurity and post-lumbar puncture headache treatment. Caffeine is also found in dietary supplements, where its “thermogenic” properties are marketed for weight loss purposes. Natural sources of caffeine include coffee beans, *Camilla sinensis* leaves (tea leaves), kola nut, and guarana seeds. Patients have presented with caffeine toxicity and atrial fibrillation after consumption of guarana extract [6]. Excessive caffeine consumption may contribute to, trigger, or exacerbate psychiatric disorders such as psychosis or mania [7]. Caffeine toxicity has been reported after mesotherapy subcutaneous injections [8]. Acute caffeine intoxication has pathophysiology, symptoms, and management similar to those of theophylline intoxication.

Recently, major clinical effects and fatalities have been reported from the use of caffeine-containing energy drinks when taken by small

children or in large quantities. In a study of approximately 3200 energy drink-related exposures reported to US poison centers over 1 year, approximately half involved children under the age of 6. Energy drinks containing ethanol were associated with a higher rate of major adverse effects, such as seizures, dysrhythmias, and tachypnea [9]. Combining ethanol with caffeine-containing energy drinks appears to be associated with decreased performance on some psychometric testing parameters, and subjects reported feeling less clear-headed and clumsier on subjective symptom assessment [10]. Caffeine was deemed an “unsafe food additive” to ethanol containing malt beverages, and in 2010 the US Food and Drug Administration issued warning letters to manufacturers of these beverages to cease marketing and distribution of such beverages. Ethanol has been banned from commercially available energy drinks marketed in the USA [11].

Severe toxicity and even fatalities have also been reported from the use of anhydrous caffeine powders that are commonly purchased on the Internet [12–14]. Caffeine may also be found as an undeclared ingredient in packages of novel psychoactive compounds and “club drugs” and may confound or contribute to the toxicity of these compounds [15–17]. Restrictions in the quantities of caffeine sold over the counter may reduce some morbidity and mortality [18]. Coffee enemas are sometimes touted as alternative cancer treatments and for relief of constipation. While caffeine toxicity has not been reported from rectal coffee instillation, thermal and chemical injury to the rectal and colonic mucosa has been [19–23].

Pentoxifylline is a xanthine derivative with hemorrheologic properties. By decreasing blood viscosity and erythrocyte deformability, it increases blood flow and tissue oxygenation. Its exact mechanism remains unknown [9]. It is used in the treatment of peripheral vascular and cerebrovascular disease to improve blood flow to ischemic areas [24]. Studies have found decreased blood viscosity due to decreased plasma fibrinogen and increased flexibility of erythrocytes, not due to vasoactive or cardioactive properties [25, 26].

Biochemistry and Pharmacology

Theophylline, caffeine, and pentoxifylline are all xanthine derivatives. Their structures closely resemble that of purines, such as adenosine (Fig. 1).

Theophylline is absorbed completely after oral therapeutic doses. For each 1 mg/kg ingested, a peak serum concentration of 2 µg/mL is expected to result. In therapeutic use, peak serum concentrations occur 1–2 h after ingestion of an immediate-release formulation and 6–8 h after ingestion of a sustained-release preparation. In overdose, sustained-release tablets may have prolonged and erratic absorption, possibly because of bezoar formation [27, 28]. Peak levels may be delayed for 24 h [29] and may continue to rise despite repeated doses of activated charcoal [30]. One case of fatal intoxication has been associated with rectal instillation of theophylline-containing tablets [31].

Theophylline has a relatively small volume of distribution (0.4 L/kg), although it tends to be larger at extremes of age (0.64 L/kg) in premature neonates [32]. It is distributed rapidly to all tissues [33]. It is metabolized by cytochrome P-450 isoenzymes 1A2, 2E1, and 3A4. Demethylation products include 1-methylxanthine and 3-methylxanthine; these metabolites are converted to 1-methyluric acid (1-MU) and 3-methyluric acid (3-MU) via xanthine dehydrogenase (Fig. 2) [34, 35].

Across the therapeutic range, theophylline elimination follows Michaelis-Menten kinetics; first-order kinetics changes to zero-order elimination as higher serum theophylline concentrations are attained. In an acute overdose, elimination can be expected to initially follow zero-order kinetics [29].

Patients taking theophylline therapeutically are at risk for developing theophylline toxicity for two reasons. First, because theophylline elimination follows Michaelis-Menten (i.e., saturable) kinetics, a small increase in dose (e.g., when a patient takes doses additional to those prescribed) may result in a disproportionately large increase in serum concentrations. Second, the rate of

[42]. Theophylline metabolism may be impaired by chronic use of St John's wort [43]. Theophylline concentrations may increase after influenza vaccination, an interaction thought to be mediated by interferon-gamma effects on CYP 2E1 activity [44]. Theophylline clearance is increased in the third trimester of pregnancy and up to 13 weeks postpartum [45]. Theophylline may increase concentrations of some drugs, such as tacrolimus [46].

Caffeine is demethylated at any of its three positions by CYP 1A2 to either theobromine, paraxanthine, or theophylline. There are minor contributions to caffeine metabolism by CYP 2A6, 2C9, 2E1, 2C8, and 3A4; xanthine dehydrogenase; and *n*-acetyltransferase (Fig. 3) [47]. Animal studies indicate increased hyperthermia, tachycardia, and seizures when MDMA or MDA are co-administered with caffeine [48]. Animal pharmacokinetic models demonstrate decreased conversion of MDMA to MDA, a CYP 1A2-mediated process, in the presence of caffeine [48]. However, one human volunteer study of MDMA users shows increased CYP 1A2 activity in the presence of caffeine [49]. Due to these conflicting results, it is thought that the increased toxicity of MDMA when combined with caffeine is likely due to a complex pharmacodynamic interaction [48].

Pentoxifylline is nearly completely absorbed after oral ingestion. It undergoes extensive first-pass metabolism to 1-[5-hydroxyhexyl]-3,7-dimethylxanthine and 1-[3-carboxypropyl]-3,7-dimethylxanthine. The half-life of pentoxifylline is 0.4–0.8 h and that of its metabolites is 1–1.6 h. Urinary excretion of pentoxifylline metabolites consists almost exclusively of 1-[3-carboxypropyl]-3,7-dimethylxanthine [24]. Increased bleeding has been reported in some patients taking pentoxifylline with and without anticoagulants such as warfarin and antiplatelet medications [24]. Drug-induced hepatitis has been reported in association with pentoxifylline. In one case biopsy demonstrated centrilobular cholestasis [50, 51].

Table 1 compares the structures, pharmacokinetics, and pharmacodynamics properties of methylxanthines. Caffeine is metabolized predominantly by CYP 1A2 and 2E1. Theophylline

is metabolized by CYP 1A2, 2E1, and 3A3. In adults, theophylline has a longer half-life than caffeine.

Pathophysiology of Toxic Effects

Therapeutic effects are mediated primarily through activity at adenosine and adrenergic receptors. Theophylline is a potent adenosine antagonist. Its beneficial effect is due primarily to antagonism of adenosine A₁ receptors in the lungs, which produce bronchodilation. Adenosine antagonism is also a major factor in producing toxicity. In the central nervous system, antagonism of A₁ receptors can result in sustained, unmodulated discharge of neurotransmitters – including glutamate, a major excitatory neurotransmitter – resulting in seizure activity. In the heart, A₁ receptor antagonism leads to an increase in the rate of discharge of cardiac pacemaker cells and increased arrhythmogenesis. Antagonism of A₂ receptors, present throughout the vascular system, results in vasoconstriction [52]. Vasoconstrictive effects have been shown to be important in the central nervous system [53] and are presumed to be important in the myocardium as well [54].

Methylxanthines exert their effects as antagonists of adenosine at adenosine receptors. Adenosine (Fig. 4) is a product of purine biosynthesis that is omnipresent in the human body and acts on any of four G protein-linked receptors: A₁, A_{2A}, A_{2B}, and A₃ (Table 2). In the central nervous system, adenosine serves as a neuromodulator [55] and has anticonvulsant properties [56]. In the heart, adenosine lowers the heart rate and atrioventricular nodal conduction and promotes microcirculatory vasodilatation. Adenosine agonists are used for pharmacologic cardiac stress testing. In the renal circulation, adenosine causes vasoconstriction. Effects of stimulating the adenosine receptor subtypes are listed in Table 2 [57, 58]. Therefore, expected clinical effects of methylxanthines are opposite those of adenosine.

Adenosine receptors A₁ and A₃ are coupled to Gi proteins and A₂ to Gs proteins. Therefore, A₁ and A₃ stimulations lead to inhibition of adenylate cyclase (AC), whose end product is

Fig. 3 Stylized liver cell showing pathways involved in the metabolism of caffeine (From: Thorn Caroline F, Aklilu Eleni, McDonagh Ellen M, Klein Teri E, Altman Russ B. “PharmGKB summary: caffeine pathway”

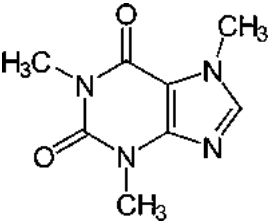

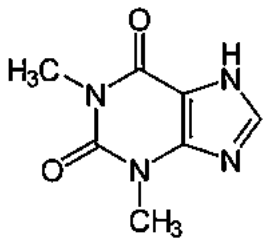

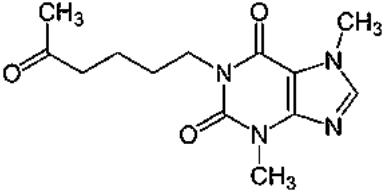

Pharmacogenetics and genomics (2012). In <https://www.pharmgkb.org/pathway/PA165884757>. Copyright PharmGKB and Stanford University, 2012. Used with permission)

cyclic AMP. When A1 and A3 receptors are antagonized, then adenylate cyclase activity would be expected to increase. A2 receptors, when stimulated, increase AC activity, so antagonism would be expected to decrease this activity. Downstream targets of cyclic AMP signaling include protein kinase A, inositol triphosphate, and protein kinase C. These enzymes are the

same as those downstream from beta-adrenergic receptors (Fig. 3) [59]. Therefore, the net result of antagonism by methylxanthines resembles beta-adrenergic stimulation.

In addition to being a potent adenosine antagonist, methylxanthines have powerful indirect adrenergic activity. Theophylline intoxication has been shown to produce increased

Table 1 Structures and pharmacokinetic data of the methylxanthines

plasma catecholamines (epinephrine and norepinephrine) in animal models [60, 61] and in case series of human victims of theophylline intoxication [62, 63]. The magnitude of catecholamine elevation and the specific catecholamine released seem to vary depending on the type of intoxication. Acute intoxication has been shown to be associated with epinephrine concentrations elevated fourfold to eightfold greater than controls and norepinephrine levels fourfold to tenfold normal [62, 63]. In a few patients with chronic overdose who have been

studied, norepinephrine and dopamine levels were elevated compared with normal controls and patients with an acute theophylline overdose [62].

Theophylline and caffeine are phosphodiesterase inhibitors at toxic concentrations. Inhibition of phosphodiesterase results in increased levels of cyclic adenosine monophosphate and augmentation of adrenergic effects. Alterations in intracellular calcium transport have also been postulated to be important in theophylline and caffeine toxicity, although this has not been well studied [64].

Fig. 4 Schematic representation of the different signaling pathways associated with adenosine receptors. Adenosine receptors are GPCRs. A1R and A3R couple to Gi/o, inhibiting AC, which will reduce cAMP levels and consequently decrease PKA activity. A2AR and A2BR are coupled to Gs, promoting AC activity and consequently PKA activity. A3R and A2BR can also couple to Gq/11, enhancing PLC activity. PLC catalyzes PIP2 into DAG and

IP3. DAG will directly activate PKC, while IP3 will increase intracellular Ca^{2+} levels. Furthermore, all adenosine receptors can activate the MAPK pathway (From Sebastiao A, Cristovao-Ferreira S, and Ribiero J. Downstream Pathways of Adenosine. In: Adenosine: A Key Link Between Metabolism and Brain Activity. Masino S and Boison D, Eds; Springer Science & Business Media, 2012 used with permission)

Clinical Presentation and Life-Threatening Complications

Organ System Effects

Methylxanthine toxicity primarily affects the gastrointestinal, cardiovascular, and central nervous systems. Characteristic metabolic disturbances, including hypokalemia and hyperglycemia, are noted frequently. Severe lactic acidosis and rhabdomyolysis have been reported. Here, theophylline is discussed as the prototypical methylxanthine.

Gastrointestinal Manifestations

Nausea and vomiting are the predominant gastrointestinal system manifestations. Vomiting is an almost universal feature of severe, acute

intoxication; it is less common after chronic intoxication [1–3, 65]. Vomiting results from gastric acid hyperstimulation [66] and central stimulation of the chemoreceptor trigger zone. Vomiting may be difficult to control and may make it impossible for the patient to tolerate activated charcoal, a potentially important therapeutic intervention [65, 67]. Hematemesis may occur as a consequence of a Mallory-Weiss tear [2, 67]. One case of pancreatitis related to a critically ill patient with theophylline toxicity has been reported [68].

Cardiovascular Manifestations

Theophylline predisposes to arrhythmias by reducing the ventricular fibrillation threshold and by nonuniformly increasing cardiac conduction, favoring reentrant arrhythmias [69]. It predisposes the heart to develop arrhythmias even at

Table 2 Functions and targets of adenosine receptors

Receptor	Second messenger	Target organs	Agonism	Antagonism
A1	Gi	Kidney	Increased proximal tubular Na transport	Diuresis
		Adipocytes	Antilipolysis	Lipolysis

therapeutic serum concentrations [70]. At toxic serum concentrations, tachyarrhythmias and hypotension are common findings [1, 3, 30]. Any type of atrial (e.g., multifocal atrial tachycardia) or ventricular tachyarrhythmias may be seen after theophylline intoxication. Death frequently results from an intractable ventricular arrhythmia [1, 3, 30]. Other factors potentially contributing to arrhythmias include coronary ischemia due to A₂ receptor antagonism, increases in circulating catecholamines, hypokalemia, and acidosis [54, 70].

The hypotension associated with theophylline intoxication is multifactorial. Vasodilatation [71, 72] is likely to be in part due to theophylline-stimulated catecholamine release and beta₂-adrenoceptor stimulation [60, 73–75]. In addition, tachyarrhythmias result in reduced filling time and decrease cardiac output; hypovolemia secondary to gastrointestinal losses and theophylline-induced diuresis also contribute to hypotension.

Central Nervous System Manifestations

Central nervous system manifestations of theophylline toxicity include agitation, tremor, and

seizures. Seizures may occur without warning, particularly in those with chronic theophylline intoxication [1]; these may be either focal or generalized. Some [76, 77], but not all [1], studies have found seizures to occur more frequently in patients with underlying neurologic disorders, such as cerebrovascular accident or seizure disorder. When seizures begin, they are frequently difficult to control [78]. Nonconvulsive status epilepticus has been reported [79].

Theophylline-induced seizures have a high morbidity and mortality. In most studies, mortality has been reported to be 10%, although 50% mortality has been reported [2]. Higher mortality and morbidity are associated with prolonged seizures [80]. In a study of children with status epilepticus from diverse causes, there was a 50% morbidity and mortality in children with status epilepticus associated with supratherapeutic theophylline concentrations compared with a 23% rate in children with status epilepticus from other causes [81]. Theophylline-induced seizures may be associated with poor neurologic outcome ranging from profound memory deficit to persistent vegetative state. Selective bilateral hippocampal lesions have been

reported after theophylline-related status epilepticus [82]. Morbidity, such as arrhythmia, has been reported even when status epilepticus has not occurred [80, 83, 84].

Metabolic Manifestations

Theophylline toxicity also is associated with hypokalemia, hyperglycemia, mild hypomagnesemia [85], and metabolic acidosis. Hypokalemia and hyperglycemia are more common in acute than in chronic intoxication [1, 2, 62, 86] and may be helpful in determining the type of intoxication if not clear by history. While not demonstrated in formal studies, it seems to reason that electrolyte abnormalities may contribute in some part to the arrhythmias and cardiac irritability seen in methylxanthine toxicity. Generally, hypokalemia is thought to be from intracellular shifting of potassium [87]. Significant alterations in pH are uncommon, although severe lactic acidosis has been reported with pH as low as 6.63 [88]. Hyperlactemia has been reported with therapeutic use of theophylline with salbutamol in an asthma exacerbation [89]. Similarly, caffeine intoxication has been associated with hyperlactemia [90]. Rhabdomyolysis and compartment syndrome have been reported after acute theophylline and caffeine intoxication [1, 2, 38, 91–93]. Caffeine poisoning has also been associated with hyponatremia [92] and acute renal failure [92, 93].

Drug Concentrations: Therapeutic and Toxic Drug Monitoring

In acute intoxication, serum theophylline concentrations correlate with the risk for major complications, although no serum concentration has been shown to have an acceptable degree of predictive sensitivity and specificity. In a series of 98 patients who were reported to a regional poison center, a serum theophylline concentration of 60 µg/mL (333 µmol/L) had a sensitivity of 90% and a specificity of 75% for identifying patients who developed major toxicity. In contrast, a serum theophylline concentration of 80 µg/mL (444 µmol/L) had a specificity of 97% but a sensitivity of only 67% [94]. Similarly, Paloucek and Rodvold [1], in a review of cases of theophylline intoxication published between 1975 and 1985,

found that seizures occurred only when the serum concentration was greater than 50–60 µg/mL (278–333 µmol/L) [1]. In a series of 14 patients who presented to an emergency department after acute ingestion, life-threatening effects (LTEs) were seen only in patients with serum concentrations greater than 80 µg/mL (444 µmol/L) [2]. A serum theophylline concentration of 43 µg/mL (239 µmol/L) has been reported with seizures after acute overdose, however [30].

For patients with chronic intoxication, age rather than serum theophylline concentration is the most important prognostic factor. In a prospective poison center-based study of 92 patients with chronic intoxication, patients older than age 60 had a 50% probability (confidence interval 38–63%) of developing LTE. Using the criterion of age greater than 60 for predicting major toxicity had a sensitivity of 80% and specificity of 62% [94]. Other case series support the correlation of advanced age with occurrence of LTE [1, 2, 80, 81]. In the only study of children, LTEs were associated with younger age, with infants younger than 1 year being at greatest risk [86]. Serum theophylline concentrations have poor predictive value in chronic intoxication. In the only study designed to study risk factors systematically, there was no correlation between serum concentration and occurrence of LTE [94]. There are reports of LTE occurring with serum concentrations in the therapeutic range of 10–20 µg/mL (56–111 µmol/L) [1, 95]. Most case series have not reported LTE, however, unless the serum theophylline concentration is greater than 30 µg/mL (167 µmol/L) [2, 3, 86, 96].

In summary, while serum concentrations generally are predictive of LTEs, they may not correlate exactly, and a patient with a severe clinical presentation must be considered to have a serious poisoning, even with a therapeutic or moderately elevated serum concentration.

Treatment

There are four components of treatment for xanthine poisoning: (1) supportive care, (2) gastrointestinal decontamination, (3) pharmacologic

treatment of manifestations, and (4) enhancement of elimination.

Indications for ICU Admission in Theophylline and Other Methylxanthine Poisoning

Seizure

Ventricular arrhythmia

Hypotension

Rising theophylline concentration despite decontamination

Supportive Care

This text presumes that appropriate supportive measures have occurred. Patients with abnormal vital signs typical of methylxanthine intoxication should be cared for in a clinical setting with cardiac, pulse oximetry, and blood pressure monitoring and qualified personnel.

It is axiomatic that crystalloid should be given to replace losses from diuresis and emesis and that continuous electrocardiographic monitoring to assess for myocardial irritability should be instituted. Isolated premature ventricular contractions that are not associated with hemodynamic compromise require no treatment. More significant signs of myocardial irritability should be treated with appropriate doses of lidocaine (Grade III recommendation). Although the proconvulsant actions of lidocaine pose a theoretical risk, there is no evidence suggesting that lidocaine is detrimental in methylxanthine toxicity when used in appropriate doses [97–99].

Gastrointestinal Decontamination

Methylxanthines are adsorbed by activated charcoal, and in one volunteer study, charcoal reduced the dose of ingested theophylline by 64% [100]. Compared with gastric lavage, activated charcoal has been shown to be superior for reducing absorption of theophylline in a simulated overdose scenario volunteer study [101]. For a patient who has ingested a large dose of methylxanthine, or who is showing signs of toxicity, administration of single-dose activated charcoal

is indicated as long as there is an intact or protected airway [102]. No clinically significant benefit has been established from the addition of cathartic to the activated charcoal [103]. Methylxanthine toxicity is often associated with nausea and vomiting which may limit activated charcoal use [65, 67]; antiemetics may facilitate administration of activated charcoal; however, the clinician should assess whether the patient's mental and airway protection status will allow for its safe administration. Ondansetron (8 mg) has been reported to be successful in terminating vomiting in a single case report of theophylline poisoning after failure of other antiemetics [104].

The American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists have recommended that whole-bowel irrigation (WBI) should be considered in an acute overdose with a sustained-release preparation [105], although an animal model of acute theophylline overdose did not show that whole-bowel irrigation significantly reduces absorption of theophylline [106]. One small human trial demonstrated decreased absorption of a 200 mg dose of sustained-release theophylline with charcoal, but no statistically significant effect of adding whole-bowel irrigation to activated charcoal [107]. Therefore, the current state of evidence does not support the routine use of whole-bowel irrigation for the treatment of methylxanthine toxicity. A bezoar should be suspected in patients who continue to have rising serum concentrations despite tolerating activated charcoal. Rarely, endoscopy has been used to remove a bezoar [28] and whole tablets [108].

Pharmacologic Management

Recommendations for pharmacologic treatment of theophylline overdose (Table 3) are based on an understanding of pathophysiology and anecdotal experience. No large series or randomized clinical trials have studied the efficacy of specific pharmacologic interventions for theophylline intoxication.

Table 3 Pharmacologic treatment in theophylline overdose^a

Effect	Agent	Dose	Comment
Emesis	Ondansetron	8 mg IV (0.15 mg/kg IV)	Cimetidine should not be used, as it inhibits metabolism of theophylline
	Ranitidine	50 mg IV (2 mg/kg)	
Seizure	Lorazepam	4 mg IV (0.1 mg/kg IV)	Other benzodiazepines may be used
	Phenobarbital	300–800 mg (20 mg/kg IV)	May augment respiratory depression
Hypotension	Propranolol	1–3 mg slow IV push (0.02 mg/kg IV)	May precipitate bronchospasm in asthmatic patients; if effective, consider infusion 5–10 mg/hr
	Esmolol	500 µg/kg over 1 min, then 50 µg/kg/min	May increase left ventricular stroke work index
			May be effective if hypotension is due to tachycardia

IV intravenous

^aNumbers in parentheses indicate pediatric dose

Vasopressors

Hemodynamic monitoring is indicated for all patients with methylxanthine poisoning. Intravenous crystalloid fluid boluses are the first-line treatment for hypotension and any volume losses from diuresis. There are no randomized controlled trials of the ideal treatment of hypotension in methylxanthine poisoning; however, one case report describes the use of esmolol, a selective beta-1 antagonist, to slow the heart rate and allow for greater ventricular filling time and stroke volume, improving cardiac output [109]. Pharmacologically, esmolol would be expected to reduce heart rate and thus possibly improve hypotension (Grade III recommendation).

Electrolytes

Hypokalemia should be treated cautiously with potassium supplementation because total body potassium is not depleted. Rather, hypokalemia results from intracellular sequestration secondary to sympathomimetic effect [110]. Cardiac dysrhythmias may occur during the treatment of acute asthma for a number of reasons, including electrolyte abnormalities due to pharmacotherapy. A comparison of two treatment regimens by a double-blind protocol found that aminophylline was not any more arrhythmogenic than standard epinephrine treatment [99].

Hyperkalemia may occur as the serum theophylline concentration decreases in a patient who is receiving potassium supplementation [111, 112] or if a patient is being treated with propranolol [113]. Administration of magnesium and sodium bicarbonate is indicated for clinically significant hypomagnesemia and acidosis (Grade III recommendation).

Arrhythmias

The initial approach to methylxanthine-induced, clinically significant cardiac arrhythmias is standard advanced cardiac life support algorithms (Grade III recommendation). Atrial tachyarrhythmias have been shown to be reversed by beta-blockers [109]. Nonspecific β -blockers, such as propranolol, should be administered cautiously to patients with asthma because they may precipitate bronchospasm. Additionally, the use of nonspecific β -receptor antagonists may lead to unopposed α -adrenergic activity, resulting in coronary vasoconstriction and left ventricular dysfunction. One animal study of caffeine toxicity described increased survival time in rats receiving either propranolol or verapamil [114]. One case report describes unsuccessful use of propranolol to control pressor-refractory hypotension, and the patient died despite this and charcoal hemoperfusion. In this case, propranolol had been given in an effort to reverse peripheral

vasodilation and reduced cardiac output ensued. Propranolol's side chain is demethylated by CYP 1A2, and though there is a possibility of pharmacokinetic drug interaction with theophylline, none has been described [115]. Esmolol, a selective β_1 -adrenoreceptor antagonist, seems to be safe to use in patients with asthma; however, their respiratory status should be monitored closely. It has been used successfully in a theophylline overdose patient with supraventricular tachycardia and hypotension [109], a finding that has been supported in an animal model [116]. Thus, esmolol is reasonable choice for the treatment of xanthine-induced tachyarrhythmias (Grade III recommendation). Esmolol may increase left ventricular stroke work index by increasing filling time; thus, hemodynamics in patients so treated should be carefully monitored [117].

Adenosine has been reported to reverse theophylline-induced paroxysmal supraventricular tachycardia at typical adult doses of 6 mg [118], although higher doses may be required [119, 120]. Adenosine is likely to be of minimal clinical usefulness, however, because of its ultra-short half-life, and continuous infusions of adenosine can lead to bronchoconstriction and atrioventricular block [120–122]. Verapamil has been used to treat multifocal atrial tachycardia [123] but has failed in the treatment of supraventricular tachycardia [30].

Hypotension

Hypotension that persists despite fluid resuscitation and treatment of clinically significant arrhythmias has been reported to be effectively treated with the α -receptor agonist, phenylephrine [124] (Grade III recommendation). Hypotension also has been treated successfully with propranolol, a nonselective beta antagonist that antagonizes β_2 -mediated vasodilation [63, 113]. Invasive cardiovascular monitoring is indicated for patients who are persistently hypotensive. One case report describes the use of an intravenous lipid emulsion [ILE] infusion (but not a bolus) combined with continuous venovenous hemodiafiltration (CVVHD) to treat refractory vasodilatation and

arrhythmias after caffeine overdose [125]. Caffeine does not inherently possess properties amenable to treatment with ILE. There is insufficient evidence to recommend the use of ILE for methylxanthine intoxication. Vasopressin has been reported to increase blood pressure to facilitate hemodialysis in near-fatal caffeine poisoning; the mechanism is purported to be vasopressin receptor subtype 1 (V1) receptor stimulation activating phospholipase C and releasing intracellular calcium stores from vascular smooth muscle [126].

Seizures

Seizures are notoriously difficult to control in patients with theophylline intoxication [78]. Although not specifically studied with methylxanthines, in most seizures of toxic origin, benzodiazepines, of which large doses may be required, are generally considered to be first-line therapy (see ► Chap. 20, “Toxicant-Induced Seizures”). Phenobarbital or other barbiturates or propofol may be used as adjunctive anticonvulsants. Barbiturates have the disadvantage of delayed onset and have a synergistic action with benzodiazepines, potentiating respiratory depression. Administration of propofol may require higher than typical dosing [127]. Phenytoin should be considered to be contraindicated based on the empirical observation that it is ineffective in the termination of theophylline-induced seizures and based on animal data suggesting increased mortality [128]. If anticonvulsants are ineffective in terminating seizures, neuromuscular blockade is indicated. In this circumstance, continued anticonvulsant therapy and continuous electroencephalographic monitoring are needed to ensure that electrical seizure activity is not occurring.

Extrapolating from experience in animal models, prophylactic administration of an anticonvulsant, either a benzodiazepine or a barbiturate, should be considered in patients at high risk for theophylline-induced seizures (Grade III recommendation). High-risk patients are those with acute overdose and with a serum theophylline concentration greater than or equal to 80 $\mu\text{g/mL}$

(444 $\mu\text{mol/L}$), patients with chronic intoxication who are older than age 60 and with a serum theophylline concentration greater than or equal to 30 $\mu\text{g/mL}$ (167 $\mu\text{mol/L}$), and patients with a history of a seizure disorder or evidence of neuromuscular excitability. Although there is no reported experience in humans to support this practice, pretreatment with anticonvulsants in animal models of acute theophylline intoxication has been shown to be beneficial [128–130]. The use of prophylactic anticonvulsants is not a substitute for and should not result in delay in instituting extracorporeal elimination when the latter is indicated.

Emesis

Emesis must be controlled to administer activated charcoal effectively and to prevent further fluid loss. Control of emesis may be difficult to achieve for most patients with theophylline intoxication [2, 30, 67]. Standard antiemetics, such as phenothiazines, are frequently ineffective [30, 67]. Additionally, phenothiazines may lower the seizure threshold significantly. Ondansetron, a 5-hydroxytryptamine antagonist that acts at the chemoreceptor trigger zone, should be considered to be the antiemetic of choice because it has been shown to reduce theophylline-associated vomiting when other antiemetics have failed [104, 131] (Grade III recommendation). Ranitidine is an important adjunct because it decreases theophylline-induced gastric hypersecretion [66] and does not inhibit cytochrome P-450 enzymes. Ranitidine has been shown to be effective in controlling emesis when used alone [132].

Enhancement of Elimination

There are three main modalities for enhanced elimination of theophylline: multiple-dose activated charcoal (MDAC), charcoal hemoperfusion, and hemodialysis.

Multiple-dose activated charcoal has been shown to reduce theophylline half-life in a case series of intoxicated patients and in human

experimental models of theophylline intoxication [133–141]. In one series of five infants, MDAC reduced the expected half-life of theophylline from 25 h to between 6.5 and 12.6 h [140]. Similarly, in a human volunteer trial, the half-life of theophylline was reduced from 6.4 to 3.3 h when MDAC was administered [142].

The optimal regimen for MDAC has been studied in human volunteers who received 6 mg/kg of aminophylline intravenously. Frequency of administration was found to be more important than the total amount of charcoal given. Administering activated charcoal every 2 h maximally increased clearance of theophylline [143]. The recommended regimen is 25 g of activated charcoal administered every 2 h until the serum theophylline concentration has declined to a level associated with clinical improvement [144]. Activated charcoal should not be used if the patient has an ileus or any other abnormality in bowel motility. As with single-dose AC, MDAC use may be limited by emesis in a patient with methylxanthine toxicity. Ranitidine may decrease some of the gastric acid hypersecretion that contributes to the vomiting in theophylline toxicity and facilitate administration of MDAC [132]. Ondansetron has been reported to be effective in one theophylline toxicity case requiring MDAC and whole-bowel irrigation [104]. If emesis is not quickly controlled, MDAC can be expeditiously administered through a naso- or orogastric tube. When MDAC is administered, it is crucial to avoid using cathartics with each dose because these may lead to life-threatening volume depletion and electrolyte abnormalities. The activated charcoal should be administered as an aqueous suspension. Suggested indications for enhanced elimination are given in Table 4. When giving MDAC, patients should undergo serial abdominal examinations to assess for the presence of intestinal pseudo-obstruction and charcoal bezoar, as these have been described in case reports as complications of MDAC therapy [145].

Extracorporeal drug removal (ECR) may be beneficial for selected patients. Acceptable ECR modalities include hemodialysis and charcoal hemoperfusion [146]. Triple-volume exchange

Table 4 Indications for enhanced elimination

Executive summary of recommendations	
1) General statement:	ECTR is recommended in severe theophylline poisoning (1C)
2) Indications of ECTR:	
ECTR is recommended for:	
[Theophylline] > 100 mg/L (555 μ mol/L) in acute exposure (1C)	
Seizures (1D)	
Life-threatening dysrhythmias (1D)	
Shock (1D)	
Rising serum [theophylline] despite optimal therapy (1D)	
Clinical deterioration despite optimal therapy (1D)	
ECTR is suggested for:	
[Theophylline] > 60 mg/L (333 μ mol/L) in chronic exposure (2D)	
Age <6 months or > 60 years old and [theophylline] > 50 mg/L (278 μ mol/L) in chronic exposure (2D)	
Gastrointestinal decontamination unable to be administered (2D)	
3) Cessation of ECTR:	
Recommended when clinical improvement is apparent OR the [theophylline] < 15 mg/L (83 μ mol/L) (1D)	
4) Choice of ECTR:	
Intermittent hemodialysis is the preferred recommended ECTR (1C)	
The following are acceptable alternatives if hemodialysis is not available:	
Hemoperfusion (1C)	
CRRT (3D)	
Exchange transfusion is an alternative to hemodialysis in neonates (2D)	
5) Miscellaneous:	MDAC should be continued during ECTR (1D)

Adapted from Ref. [153]

transfusion was used successfully in a premature infant [147, 148], but may be impractical in an adult patient, especially when other ECR modalities are available. Peritoneal dialysis removes theophylline but too slowly to have a role in the treatment of theophylline intoxication [149]; however, it has been used in premature neonates when vascular access for hemodialysis (HD) is impractical [149]. The molecular adsorbent recirculating system (MARS(tm)) has been reported in one case to be associated with increased clearance. Ideally, ECR should begin before LTEs fully evolve because numerous case series and case reports have shown that ECR does not reliably terminate LTEs once they begin [1, 2, 30, 146, 147,

150]. Patients have died or experienced significant neurologic disability despite the institution of ECR [1, 2, 30, 151].

Important differences exist between hemodialysis and hemoperfusion. Historically, hemoperfusion is associated with a higher rate of clearance than hemodialysis. Hemoperfusion has been shown to decrease the elimination half-life of theophylline to 1.23 ± 0.31 h versus 2.39 ± 1.14 h for hemodialysis [146]. This difference may now be obviated by the availability of high-flux hemodialysis cartridges; however, this issue has not been formally studied. Hemoperfusion has many disadvantages, however. It is not available in all centers and is associated with complications such as bleeding, thrombocytopenia, and hypocalcemia in 40–60% of patients undergoing the procedure [152, 153]. In contrast, hemodialysis is readily available at most centers and has a lower complication rate [147, 153]. ECR is discussed in more detail in ► Chap. 12, “Extracorporeal Substance Removal.” Saturation of the hemoperfusion cartridge may require the use of multiple cartridges to treat a single patient. As an illustrative case, one report describes theophylline toxicity in a 61-year-old male treated with two rounds of multidose activated charcoal, intermittent HD, whole-bowel irrigation, two sessions of sustained low-efficiency dialysis (SLED), and continuous venovenous HD (CVVHD) over the course of 48 h [154]. The authors describe theophylline clearance of 88–103 ml/min on HD (blood flow 250 ml/min) and 53–71 ml/min on SLED (blood flow 180 ml/min).

In 2012, the Extracorporeal Treatment in Poisoning (EXTRIP) working group convened, representing a collaboration across the fields of medical toxicology, clinical pharmacology, nephrology, and critical care medicine. The intent of this group was to critically assess the literature on the use of extracorporeal therapies for drug removal in poisoning. Extracorporeal therapies for methylxanthine poisoning were compared and extensively reviewed in 2015 [153]. Both caffeine and theophylline are small, 50% protein-bound, small-Vd molecules. These properties make

methylxanthines amenable to hemodialysis. With high-efficiency membranes, clearance of theophylline by hemodialysis can increase from 30 to 150 ml/min compared with endogenous clearance [153]. Extracorporeal techniques should be considered for any patient who is at high risk for LTEs (see Table 4). As previously discussed, in an acute ingestion, high-risk patients include patients with a theophylline serum concentration greater than 100 µg/mL (444–555 µmol/L). In chronic intoxication, patients who are older than age 60 or younger than 6 months and who have supratherapeutic levels are at risk. A summary of EXTRIP recommendations is listed in Table 4.

Although hemoperfusion is more efficient than hemodialysis at removing theophylline, it has not been shown to be better at improving clinical outcome. In the only study to compare clinical outcomes of theophylline-poisoned patients treated with either hemoperfusion or hemodialysis, there was no significant difference in the numbers of patients who had major toxicity during or after the procedure [146]. This study must be interpreted with some caution because patients were not assigned randomly to treatment groups, and it had limited power.

It seems reasonable to have a low threshold to perform hemodialysis for high-risk patients given the risks of hemoperfusion, the poor specificity of risk factors, and the lack of demonstrable benefit between hemodialysis and hemoperfusion. For patients who are already manifesting LTEs, however, hemoperfusion is the best choice given its higher clearance. If hemoperfusion is not immediately available, hemodialysis should be instituted promptly.

Common Errors in the Treatment of Methylxanthine Poisoning

Not instituting hemodialysis in a patient experiencing a life-threatening event if hemoperfusion is unavailable

Not monitoring serum concentrations closely (every 2 h)

Not monitoring serum concentrations for 24 h after an overdose of a sustained-release preparation

Other Methylxanthines: Caffeine and Pentoxifylline

Caffeine is found in numerous prescription and nonprescription products. Chronic ingestion may produce caffeinism, a symptom complex consisting of irritability, insomnia, anxiety, and chronic abdominal pain. In contrast to theophylline, life-threatening toxicity has not been reported after chronic ingestion of caffeine. Clinical effects after acute overdose of caffeine however are similar to symptoms of acute theophylline toxicity. Metabolic acidosis [155], seizures [155, 156], and ventricular arrhythmias [155, 157] all have been reported. Caffeine poisoning also has been associated with excessive catecholamine release similar to that seen with theophylline poisoning [75]. Fatal oral doses of caffeine have ranged from 5–50 g [158–160]. Fatalities have been associated with serum caffeine concentrations ranging from 80–1560 µg/mL [161], although concentrations of 297 µg/mL have been associated with survival after hemoperfusion [157].

Treatment of acute caffeine overdose is similar to that for theophylline intoxication. Several case reports have shown that caffeine is removed effectively by hemoperfusion [157, 161]. A serum concentration level greater than or equal to 120 µg/mL has been cited as a criterion for extracorporeal removal. Since serum caffeine measurement is not performed by most hospital laboratories and requires sending a sample to a reference laboratory, the decision to perform hemodialysis for caffeine poisoning is usually based on the patient's clinical picture.

Pentoxifylline is a xanthine derivative used in the treatment of peripheral vascular disease. Experience in overdose is limited. Acute overdose has been associated with hypokalemia, hyperglycemia, atrioventricular block, and hypotension [162–165]. Death has occurred after massive overdose [166]. Toxicity from chronic use has not been reported. Treatment is primarily supportive. Hypotension may be treated with crystalloid and seizures treated with benzodiazepines or phenobarbital. In one case of massive pentoxifylline ingestion resulting in shock, dialysis clearance was calculated at 154 ml/min. The patient survived without sequelae [167].

Special Populations

In older children and adults, 90% of theophylline is metabolized, and 10% is excreted unchanged in the urine. In neonates and young children, 50% of theophylline is hepatically metabolized with the remainder excreted unchanged in the urine [33]. Unlike adults, in neonates theophylline does have some methylation to caffeine during biotransformation, and this mechanism matures at 50–55 weeks postconceptional age [168, 169]. Theophylline has a prolonged half-life in patients at extremes of age. The half-life in neonates is 25 h, and the half-life in adults older than age 60 years is 10 h. The half-life for patients 16–60 years old is 8 h.

An 11-week pregnant female patient with intentional theophylline overdose received and tolerated hemodialysis followed by extended dialysis. Theophylline clearance was approximately 40 ml/min. Obstetrical examination prior to hospital discharge revealed a normal fetus; however, the patient terminated the pregnancy electively, as this was the original intent of her overdose [170].

The discovery of chlorpromazine and other traditional antipsychotic agents in the early 1950s revolutionized the management of schizophrenia and led to a dramatic reduction in the number of hospitalizations necessary for patients with psychosis. Shortly after their introduction, however, it was noted that these agents often produced disabling neurological side effects (e.g., sedation, extrapyramidal side effects [EPS], tardive dyskinesia [TD]) and were ineffective against the negative symptoms (e.g., anhedonia, apathy, inactivity, poverty of thought, social withdrawal) and neurocognitive deficits of schizophrenia. Initially, it was thought that EPS were linked inextricably to antipsychotic drug action. The introduction of clozapine in 1990 and other so-called atypical agents shortly thereafter has further revolutionized the management of schizophrenia. Compared with traditional antipsychotics, atypical agents produce minimal EPS at clinically effective antipsychotic doses and seem to be more effective for the negative symptoms and neurocognitive deficits of schizophrenia. This chapter describes in detail the pharmacology and toxicology of traditional and atypical antipsychotic agents.

The antipsychotics commonly are referred to either as *neuroleptics*, owing to their propensity to cause EPS, or as *major tranquilizers*, owing to their ability to cause sedation. These terms are misleading, however, because they refer to non-essential features of these agents. The newer atypical agents separate therapeutic from adverse effects; they are more likely to produce antipsychotic effects without producing EPS or sedation. The term *antipsychotic* is preferred by some experts but also is misleading [1]. Although these agents are used primarily to treat schizophrenia and other psychotic disorders, they also are used to facilitate induction of general anesthesia and to treat the manic phase of bipolar illness, agitated behavior, drug-associated hallucinations and delirium, migraine and tension headaches, nausea and vomiting, intractable hiccoughs, pruritus, and many extrapyramidal movement disorders (e.g., tics, chorea). Currently, the terms *neuroleptic* and *antipsychotic* may be used interchangeably to classify these agents.

Poisoning by antipsychotic agents may occur after therapeutic doses or accidental or intentional overdose. Toxicity often results from an extension of pharmacological actions and primarily manifests as neurological and cardiovascular abnormalities. Antipsychotic agents have a wide therapeutic index; death after overdose is rare, particularly if medical care is initiated in a timely manner. Death most commonly occurs when antipsychotics have been coingested with other agents, although relative rates may be higher when certain agents such as chlorpromazine or thioridazine are ingested alone or in combination with alcohol [2–4]. It has been estimated that the most toxic antipsychotic agents cause 1 death from poisoning for every 1000 patient-years of use [2]. Of 2,275,141 human drug exposures reported to the National Poison Data System in 2012, antipsychotics were among the top 5 substance classes most frequently cited (6.05%), with sedatives/hypnotics/antipsychotics implicated in 405 fatalities [5].

Classification

Currently, more than 40 antipsychotics are clinically available worldwide, and numerous others are in various stages of development. Antipsychotics are classified most commonly by structure, pharmacological profile, and whether they are typical (traditional, conventional) or atypical (novel, second-generation). Antipsychotics are a structurally diverse group of heterocyclic compounds, with at least 14 different classes and derivatives available worldwide (Table 1). The phenothiazine and thioxanthene agents are subdivided further into three groups (aliphatic, piperidine, and piperazine) based on side-chain substitution of the central ring (Fig. 1). The nature of the substitution influences pharmacological activity. Compared with the piperazine subclass, aliphatic (e.g., chlorpromazine) and piperidine (e.g., thioridazine) phenothiazines have lower antipsychotic potency and a lower incidence of EPS but have a higher incidence of sedation, hypotension, and anticholinergic effects [6]. Aside from the phenothiazine class,

^aA higher numerical value indicates greater binding affinity (greater antagonism) at D₂-receptor. Binding affinity (potency) at D₂-receptor correlates with daily dose range. 0 = minimal to none; 1+ = low; 2+ = moderate; 3+ = high to very high

^bNot currently available for clinical use in the United States

^cWithdrawn from market in many countries, including the United States

structure-activity relationships have not been elucidated for most antipsychotics. Antipsychotic classification based on chemical structure has little clinical utility.

It is more useful to classify antipsychotics based on relative receptor binding profiles (Table 2). Because clinical toxicity is often the result of exaggerated pharmacological activity, knowledge of an antipsychotic's relative receptor binding can be used to predict adverse effects that will occur after therapeutic doses and overdose [7–9].

Clinically, agents are considered atypical if they

1. Produce minimal EPS at clinically effective antipsychotic doses
2. Have a low propensity to cause TD with long-term treatment
3. Are effective for treating the positive (delusions, disorganized behavior, hallucinations) and negative symptoms of schizophrenia [1, 7–9, 17, 18]

Clinical Pharmacology

D₂-dopaminergic receptor antagonism (Fig. 2) seems to be necessary for antipsychotic effects; currently, there is no effective antipsychotic

devoid of this property [1, 6–8]. Antipsychotics bind to and antagonize presynaptic (autoreceptor) and postsynaptic D₂-receptors [6]. Initially, this antagonism stimulates dopamine neurons to synthesize and release more dopamine. With continued antipsychotic treatment, however, depolarization inactivation occurs, and decreased production and release of dopamine occur along with continued postsynaptic D₂-receptor antagonism [6, 18].

For most antipsychotics, the affinity (potency) for the D₂-receptor correlates with the daily dose used to treat schizophrenia and the likelihood of producing EPS [1, 8, 20]. Antagonism of mesolimbic D₂-receptors is believed to mediate antipsychotic effects (positive symptom amelioration). Based on in vivo radioligand binding studies with positron emission tomography (PET), the therapeutic effects of antipsychotics correlate with 70% or greater mesolimbic D₂-receptor occupancy [7, 21]. Simultaneous antagonism of mesocortical D₂-receptors, however, is believed to exacerbate cognitive impairment and the negative symptoms of schizophrenia [22]. Blockade of nigrostriatal D₂-receptors produces EPS (e.g., acute dystonia, parkinsonism, akathisia, and tardive dyskinesia). Agents with high affinity for D₂-receptors (e.g., fluphenazine, thiothixene, haloperidol) have a high likelihood of

Fig. 1 Chemical structures of representative antipsychotic agents

producing EPS [7]. Agents with low D_2 -receptor affinity (e.g., clozapine, quetiapine) or agents that selectively antagonize limbic D_2 -receptors over receptors in the nigrostriatum (e.g., sulpiride, remoxipride, raclopride) are less likely to produce EPS [1, 8, 9, 17, 18]. Data from PET studies show that EPS are seen with nigrostriatal D_2 -receptor occupancy at 80% or greater [7, 21]. At therapeutic doses of most conventional antipsychotics, there is minimal separation of D_2 -receptor

occupancies in the mesolimbic and nigrostriatal areas [21].

Blockade of D_2 -receptors in the area postrema (chemoreceptor trigger zone) of the medulla oblongata mediates the antiemetic action of antipsychotics. Antagonism of D_2 -receptors in the anterior pituitary (tuberoinfundibular pathway) stimulates prolactin secretion and may result in galactorrhea, gynecomastia, menstrual changes, and sexual dysfunction [7]. D_2 -receptor blockade

^aRelative neuroreceptor affinity (neuroreceptor affinity at receptor X/dopamine D₂-receptor affinity) indicates relative receptor antagonism at therapeutic (D₂-blocking) antipsychotic doses. 0 = minimal to none; 1+ = low; 2+ = moderate; 3+ = high; 4+ = very high

^bA higher M₁ and 5-HT₂ relative neuroreceptor affinity confers a lower EPS risk

Fig. 2 The release and inactivation of dopamine and blockade of the D₂-receptor by antipsychotics. *COMT* catechol O-methyltransferase, *HVA* hydroxyvanillic acid (From Brody et al. [19])

in the anterior hypothalamus impairs temperature regulation and may result in hypothermia or hyperthermia, depending on ambient temperature [6]. D₂-receptor antagonism in the hypothalamus and nigrostriatum mediates the neuroleptic malignant syndrome (see ► Chap. 31, “**Neuroleptic Malignant Syndrome**”), a rare hyperthermic condition associated with antipsychotic therapy.

A novel class of antipsychotic agents, called dopamine system stabilizers, has recently emerged. These agents (e.g., aripiprazole) function as partial agonists of the D₂ and 5-HT_{1A}

receptors with antagonism of the 5-HT_{2A} receptor. They reduce dopaminergic neurotransmission when such activity is excessive and enhance dopaminergic activity when such activity is deficient. They work to restore dopamine neurotransmission to the normal range and provide antipsychotic effects while minimizing adverse effects from excessive D₂-receptor antagonism [23, 24].

Antipsychotics are competitive antagonists at a wide variety of neuroreceptors; each agent has a unique pharmacological profile that determines its clinical profile. Because D₂-receptor potency closely correlates with the dose used to treat psychosis, the likelihood of effect from other neuroreceptors at a given dose depends on their binding affinity relative to that of the D₂-receptor (see Table 2) [7, 25]. Relative binding affinity data can be used to predict adverse effects at therapeutic doses and overdose. Relative binding affinity data can be used to predict adverse effects in overdose, which are typically an extension of effect at therapeutic doses. Agents with high relative α_1 -adrenergic antagonism (e.g., aliphatic and piperidine phenothiazines, clozapine, olanzapine, risperidone, ziprasidone, sertindole) are likely to produce orthostatic hypotension, reflex tachycardia, miosis, and nasal congestion. High relative α_2 -adrenergic receptor antagonism (e.g., clozapine, risperidone) may result in sympathomimetic effects (i.e., tachycardia). High relative H₁-histamine receptor binding (e.g., aliphatic and piperidine phenothiazines, clozapine, loxapine, olanzapine, quetiapine) produces central nervous system (CNS) depression, appetite stimulation, and hypotension. Agents with high relative M₁-muscarinic receptor binding (e.g., aliphatic and piperidine phenothiazines, clozapine, olanzapine) produce central and peripheral anticholinergic stigmata (e.g., agitation, blurred vision, delirium, dry skin and mucous membranes, hallucinations, ileus, mydriasis, tachycardia, urinary retention). Sialorrhea, a feature unique to clozapine, likely is mediated by its partial agonism at M₁- and M₄-receptors [7]. High relative potencies at M₁-receptors and 5-HT_{1A}- and

3. D₂-receptor, 5-HT_{1A}-receptor partial agonists, 5-HT_{2A}-receptor antagonists (e.g., aripiprazole), also called *serotonin-dopamine system stabilizers*
4. Broad-spectrum, multireceptor antagonists (e.g., clozapine, olanzapine, quetiapine) [9, 31]

Characteristics Associated with Atypical Behavior of Antipsychotics

Low D₂-receptor potency (high milligram drug dosing)

Low D₂-receptor occupancy (<70%) by positron emission tomography in mesolimbic and nigrostriatal areas at therapeutic drug doses

High affinities for M₁-, D₁-, 5-HT_{1A}-, and 5-HT_{2A}-receptors relative to D₂-receptors

Selective mesolimbic D₂-receptor antagonism

Broad multireceptor antagonism

Partial agonist activity at D₂- and 5-HT_{1A}-receptors

Minimal propensity to elevate serum prolactin concentrations

Adapted from Refs. [7–9, 17, 18, 21, 26, 27].

Antipsychotics with a high relative 5-HT_{2A} binding affinity (5-HT_{2A}-to-D₂-receptor binding ratio >1) have a lower likelihood of producing EPS and mitigate the negative symptoms of schizophrenia by disinhibiting the dopamine system in the striatum and prefrontal cortex (see Fig. 3) [26–28]. Normally, dopamine neurons in the nigrostriatum and prefrontal cortex are inhibited by serotonin heteroreceptors. 5-HT₂-Receptor antagonism releases dopamine neurons from this inhibition (disinhibition) and ameliorates the effects of D₂-receptor blockade. 5-HT_{1A}-Autoreceptor agonism produced by certain atypical antipsychotics (e.g., aripiprazole, clozapine, ziprasidone) or stabilizers (e.g., aripiprazole) additionally releases dopamine neurons from this inhibition and mitigates EPS (see Fig. 3) [18, 26, 27]. 5-HT_{2A}-Receptor antagonism in the limbic system seems to have an independent antipsychotic effect [18, 22]. Serotonin-dopamine

antagonists (e.g., amperozide, clozapine, olanzapine, risperidone, sertindole, ziprasidone) may be given at smaller doses and produce a lower incidence of EPS while maintaining clinical effectiveness.

Pathophysiology of Therapeutic and Toxic Effects

The aliphatic and piperidine phenothiazines (e.g., chlorpromazine, thioridazine, mesoridazine) have a direct negative inotropic action and quinidine-like (type IA) antiarrhythmic effect on the heart [6]. These agents bind to inactivated fast-sodium channels responsible for membrane depolarization and potassium channels responsible for membrane repolarization [32–34]. This sodium channel blockade is voltage and rate dependent; block is enhanced greatly at less negative membrane potentials and faster heart rates [32]. Conduction disturbances are more apparent for drugs that also produce a tachycardia (e.g., drugs with anticholinergic properties). Potassium channel blockade is concentration, voltage, and reverse frequency dependent; block is enhanced at higher concentrations, at less negative membrane potentials, and at slower heart rates [33, 34]. Drugs that prolong cardiac repolarization commonly do so by blocking the *HERG*-encoded delayed rectifier, voltage-gated potassium channel. This mechanism has been demonstrated in vitro and correlated clinically with QT prolongation with pimozide, thioridazine, and sertindole and is suspected to be at play with numerous other antipsychotics [33]. While most QT prolonging drugs inhibit I_{Kr}, the potency of this inhibition does not clearly correlate with degree of QT prolongation or risk of developing ventricular dysrhythmia (torsades de pointes) [34].

Certain antipsychotics (e.g., haloperidol, mesoridazine, pimozide, and thioridazine) also are calcium channel antagonists [35, 36]. Pimozide is known to antagonize calmodulin and T-type calcium channels [37]. Electrophysiological effects variably include a depressed rate of phase 0 depolarization, depressed amplitude and duration of phase 2, and prolongation of phase

3 repolarization. Early afterdepolarizations that result from blockade of rectifying potassium channels may trigger ventricular arrhythmias, particularly torsades de pointes.

Antipsychotics produce hypotension from depressed peripheral vasomotor tone (from α_1 -adrenergic blockade), central vasomotor reflex depression, and direct myocardial depression. Hypotension is most commonly orthostatic and occurs during initial therapeutic dosing or shortly after acute overdose with certain agents.

Antipsychotics produce dose-related electroencephalographic (EEG) changes and are believed to lower the threshold for new-onset seizures and recurrent seizures in epileptic patients [38–41]. The seizures are dose related [39–41]. For most antipsychotics, however, the risk of seizures is low, even after overdose [3]. Clozapine, loxapine, and chlorpromazine are the antipsychotics most commonly associated with seizures after therapeutic doses and overdose [38–42]. Clozapine and chlorpromazine also induce the most striking EEG alterations when schizophrenic patients are given antipsychotics in therapeutic doses [38–41]. The mechanisms by which antipsychotics lower the seizure threshold are not well understood. GABA_A-receptor antagonism, norepinephrine reuptake inhibition, and membrane-destabilizing activity (altered ionic flow through channels) may mediate seizures for certain agents. The GABA_A antagonists clozapine and loxapine (the latter from its active metabolites, amoxapine and hydroxymoxapine) also produce dose-related inhibition of norepinephrine reuptake, which may account partly for the high incidence of seizures with these agents.

Normal extrapyramidal motor function requires a balance among the excitatory nigrostriatal dopaminergic neurons and inhibitory intrastriatal cholinergic neurons, raphistriatal and raphe nigral serotonergic neurons, and GABAergic striatonigral neurons (see Fig. 3) [18, 26–29]. Numerous other neurotransmitter pathways (e.g., noradrenergic, σ , D₁, dopaminergic, and *N*-methyl-D-aspartate [NMDA] glutamatergic) converge on various basal ganglia nuclei to modulate extrapyramidal movement

further [18, 29]. All antipsychotics seem to produce EPS by nigrostriatal D₂-receptor blockade [7]. This blockade leads to striatal cholinergic excess and signs and symptoms of EPS [43, 44]. Any agent that prevents cholinergic excess by balancing D₂-receptor blockade with M₁-receptor blockade at therapeutic doses is less likely to induce EPS (less relative dopamine antagonism in the nigrostriatum) [7]. Similarly, agents with high relative 5-HT₂ antagonism or 5-HT_{1A} agonism release the nigrostriatal dopamine system from inhibition, prevent cholinergic excess, and ameliorate EPS [18, 26–28]. Agents with low D₂-receptor potency in the nigrostriatum are unlikely to result in depolarization inactivation, receptor alterations, and signs of acute and chronic EPS [18]. σ - and NMDA-receptor antagonism modulates the dopaminergic-cholinergic balance to increase the likelihood of acute dystonia, whereas α -adrenergic and D₁ antagonism seem to protect against the development of acute dystonia [18, 29, 45].

Although parkinsonism is known to result from decreased nigrostriatal dopaminergic activity, the pathophysiology of other extrapyramidal syndromes has not been elucidated fully [46]. Akathisia is possibly the manifestation of mesocortical D₂-receptor blockade [46]. Similar to parkinsonism, acute dystonic reactions (DRs) may result from decreased dorsal striatal dopaminergic activity. Paradoxically, acute DRs alternatively may result from increased nigrostriatal dopaminergic activity that occurs as a compensatory response to antipsychotics [46, 47]. Acutely, postsynaptic D₂-receptor blockade produced by antipsychotics is matched by increased presynaptic dopamine synthesis and release (see Fig. 2). As midbrain concentrations of the antipsychotic decline hours to days after a dose, a state of dopamine excess develops, and sustained muscular contraction (dystonia) occurs [44, 45]. TD is likely a compensatory response to prolonged D₂-receptor antagonism by antipsychotics. Upregulated postsynaptic processes create a state of dopamine supersensitivity and an exaggerated response despite smaller quantal releases of dopamine [6, 46, 47]. An alternative theory postulates that TD results from the neurotoxic effects of free radicals, which are produced by increased

dopamine metabolism associated with chronic antipsychotic D₂-receptor blockade [48].

Pharmacokinetics

The pharmacokinetics of antipsychotics are complex. Although the pharmacokinetic parameters are similar for most classes of agents, there is substantial interindividual variability. Absorption is nearly complete after oral administration, but bioavailability is erratic and unpredictable (range, 10–70%) as a result of extensive first-pass hepatic metabolism and interactions of intestinal transport proteins such as P-glycoprotein [49, 50]. Bioavailability is increased four to ten times after intramuscular administration. Plasma concentrations peak 1–6 h after oral therapeutic dosing, 0.5–1 h after immediate-release intramuscular administration, and within 24 h of intramuscular administration of sustained-release preparations [49, 50]. Oral inhalation of loxapine results in rapid absorption with peak serum concentrations at 2 min [51]. Sustained-release (depot) preparations are made by esterifying the hydroxyl group of an antipsychotic (e.g., fluphenazine, haloperidol) with a long-chain fatty acid (e.g., enanthate or decanoate). After oral overdose, absorption occurs more rapidly, but peak plasma concentrations are delayed; clinical effects occur sooner and last longer.

Most antipsychotics are highly lipophilic, are highly protein bound (75–99%), and accumulate in the brain and other tissues [6, 49, 50]. Volumes of distribution are large, and plasma concentrations after therapeutic doses are low (less than one to several hundred nanograms per milliliter). These pharmacokinetic characteristics make significant extracorporeal removal by hemodialysis and hemoperfusion impossible. Most antipsychotics readily cross the placenta to enter the fetal circulation and are secreted into breast milk. All antipsychotics are eliminated predominantly by hepatic metabolism. The main routes of metabolism are oxidation by cytochrome P-450 mixed-function oxidases (CYP) or flavin-containing monooxygenase (FMO), hydroxylation, sulfoxidation, *N*-dealkylation, and

conjugation [50, 52]. Metabolites commonly are active and metabolized further in the liver or excreted in the urine or bile. Large interindividual variation in the biotransformation of antipsychotics results in substantial differences in steady-state plasma concentrations with fixed therapeutic dosing [6, 49, 50, 52, 53]. In addition, many antipsychotics have metabolites that are not readily measured but are pharmacologically active. There is often little correlation among antipsychotic dose, serum concentrations, and clinical effects [49, 50, 52, 53]. Elimination half-lives typically range from 18 to 40 h and allow for once-daily dosing for many antipsychotics. Depot preparations have elimination half-lives of 7–21 days [49] (Table 3).

Drug Interactions

When antipsychotics are coadministered with other drugs, clinically significant interactions may occur [54]. Interactions may be additive or antagonistic and pharmacodynamic or pharmacokinetic. These interactions are most likely to be of clinical concern when therapy is begun or discontinued. The CNS and respiratory depressant effects of antipsychotics may be potentiated by alcohols, antihistamines, antidepressants, opiates, and sedative-hypnotics. Fatal cardiorespiratory arrest has been reported to occur when therapeutic doses of clozapine have been taken with diazepam and lorazepam [55, 56]. Exaggerated anticholinergic effects may occur when certain antipsychotics are coadministered with tricyclic antidepressants, antihistamines, antiparkinsonian agents, and certain skeletal muscle relaxants (e.g., cyclobenzaprine). The hypotensive effects of antipsychotics with α_1 -antagonist properties may be potentiated when coadministered with antihypertensives (e.g., prazosin) with similar pharmacological properties. The dopamine receptor-blocking effects of antipsychotics antagonize the effects of levodopa and dopamine agonists used to treat patients with Parkinson's disease. Mesoridazine or thioridazine may potentiate the cardiotoxicity of other type IA antiarrhythmic agents (e.g., quinidine, tricyclic

Table 3 Pharmacokinetics of commonly used antipsychotics

Antipsychotic Agent	t_{\max} (hr)	$t_{1/2}$ (hr) (mean)	Protein Binding (%)	V_d (L/kg)	Route of metabolism	Active metabolite

antidepressants) and vice versa. Certain antipsychotics (e.g., haloperidol, sertindole, thioridazine) may potentiate the QT prolongation produced by other cardioactive agents.

The addition of selective serotonin reuptake inhibitors (e.g., fluoxetine) to patients taking antipsychotics may precipitate EPS. When combined with antipsychotics, lithium may precipitate a toxic syndrome that resembles neuroleptic malignant syndrome [54].

The principal pharmacokinetic interactions that occur between antipsychotics and other drugs result from hepatic CYP P-450 enzyme induction and inhibition (Table 4) [50, 52, 54, 57]. Because many antipsychotics are metabolized by CYP2D6 and CYP1A2 enzymes, their clearance may be decreased significantly when coadministered with inhibitors of these enzymes, such as fluoxetine or paroxetine. Although these interactions occur frequently and often go unnoticed, they occasionally may result in clinically significant effects. Clozapine toxicity has been reported after coadministration with the CYP1A2 inhibitors cimetidine, erythromycin, and fluvoxamine [58–61]. Clarithromycin, a CYP3A4 and CYP1A2 inhibitor, can increase plasma concentrations of pimozide and can result in significant increases in the QT_c interval in human volunteers given a single dose of pimozide [62]. Selective serotonin reuptake inhibitors block CYP2D6 and may precipitate aripiprazole, chlorpromazine, clozapine, haloperidol, olanzapine, perphenazine, risperidone, quetiapine, and thioridazine toxicity [50, 52, 54, 57, 63]. In particular, selective serotonin reuptake inhibitors may precipitate thioridazine cardiotoxicity by increasing plasma concentrations of the unchanged parent drug and shunting metabolism to the cardioactive ring-sulfoxide metabolite. Conversely, the clearance of many antipsychotics may be increased significantly when coadministered with certain CYP isoenzyme inducers. Anticonvulsants (e.g., carbamazepine, phenytoin, phenobarbital) stimulate CYP3A4 and may decrease plasma concentrations of clozapine, olanzapine, and quetiapine. Cigarette smoking induces CYP1A2 and increases clearance of chlorpromazine, clozapine, fluphenazine, haloperidol, olanzapine, and numerous other antipsychotics [50]. Knowledge of

the receptor profile and pharmacokinetic parameters of a drug facilitates recognition and treatment of clinically significant drug interactions.

Clinical Presentation

Overdose

After accidental or intentional overdose, most patients remain asymptomatic or develop only mild toxicity [5]. Toxic effects are commonly an exaggeration of pharmacological effects. Clinical effects typically begin within 30–90 min of ingestion and include CNS and consequent respiratory depression, miosis or mydriasis, hypertension or orthostatic hypotension, sinus tachycardia, agitation, confusion, delirium, anticholinergic stigmata, myoclonic jerking, seizures, hyperthermia or hypothermia, cardiac conduction disturbances, and atrial and ventricular arrhythmias. Rarely, pulmonary edema may occur [64, 65]. Peak toxic effects are usually evident within 2–6 h, and resolution of serious toxicity usually occurs by 24–48 h. CNS depression is the most frequent clinical finding in overdose [3, 66–70]. CNS effects may range from lethargy, slurred speech, ataxia, and confusion in mild poisoning to deep coma with apnea and loss of brainstem and deep tendon reflexes in severe poisoning. Anticholinergic manifestations are frequent after overdoses with chlorpromazine, clozapine, mesoridazine, olanzapine, and thioridazine. Rarely, a post-injection delirium/sedation syndrome (PDSS) has been described shortly after injection of long-acting intramuscular olanzapine pamoate. It is characterized by sedation, confusion, slurred speech, ataxia, or coma, effects consistent with those demonstrated following olanzapine overdose. It is rare (observed in 0.07% of injections), occurs within seconds to 5 h (median onset time of 25 min) of injection, and is presumed to occur due to unintended intravascular injection of a portion of the olanzapine dose [71–73]. Sinus tachycardia is a frequent finding with chlorpromazine, clozapine, mesoridazine, olanzapine, quetiapine, risperidone, and thioridazine. Miosis is more likely to occur in severely poisoned patients; it has been

Table 4 Pharmacokinetic drug interactions of antipsychotics

Antipsychotic		Interacting drug(s)	Drug effect

described in greater than 70% of patients poisoned with phenothiazines and has been noted frequently in patients poisoned with clozapine, olanzapine, and quetiapine (agents with greater alpha blockade relative to antimuscarinic activity) [67, 68, 70, 74]. Although acute EPS are often idiosyncratic reactions that follow therapeutic antipsychotic doses, these effects also may be dose related and have occurred after overdose with many antipsychotics [66, 75, 76]. EPS may be the presenting manifestation in a child after accidental antipsychotic poisoning [75–77]. Sialorrhea, a feature unique to clozapine, has been observed in 13% of patients poisoned with this agent [67, 75]. Acute pulmonary edema has been described after overdose of chlorpromazine, clozapine, haloperidol, and perphenazine [64, 65]. Rhabdomyolysis, myoglobinuria, and acute renal failure have occurred in patients with repetitive seizures after loxapine overdose [42, 78].

Antipsychotics have a relatively high therapeutic index, particularly when compared with certain other psychotropic medications, such as tricyclic antidepressants. Overdoses of antipsychotics are rarely fatal [5]. Death most frequently results from respiratory arrest (before medical intervention), arrhythmias, or aspiration-induced respiratory failure [6]. The toxic and lethal doses are highly variable and depend largely on agent identity, the presence of coingestants, age and habituation of the patient, and time to treatment. Children and nonhabituated adults are more sensitive to the toxic effects of these agents than individuals who have taken the agents on a long-term basis before an acute overdose. Higher-potency antipsychotics (e.g., fluphenazine, thiothixene, haloperidol) are safer after overdose than low-potency, multireceptor agents (e.g., chlorpromazine, thioridazine, clozapine). These latter agents are more likely to produce respiratory depression, seizures, and cardiovascular toxicity. The ingestion of a single tablet of chlorpromazine, clozapine, loxapine, mesoridazine, olanzapine, or thioridazine may cause serious toxicity in a toddler. Coma and respiratory arrest have been reported after the ingestion of 100 and 200 mg of clozapine, respectively, in toddlers [75]. Pronounced CNS sedation and anticholinergic delirium have

occurred after the ingestion of 7.5–15 mg of olanzapine in children [79, 80]. Death of an infant was reported after the ingestion of 350 mg of chlorpromazine [81]. Adult fatalities have been reported after the ingestions of 2 g of chlorpromazine and clozapine, 2.5 g of loxapine and mesoridazine, 600 mg of olanzapine, and 1.5 g of thioridazine [81–83]. Other patients have survived much larger ingestions.

Cardiovascular Toxicity

Orthostatic hypotension and sinus tachycardia are frequent clinical manifestations [3, 66, 67, 69, 70, 75, 76, 79–81]. Electrocardiogram (ECG) abnormalities include prolongation of the PR, QRS, and QT intervals; T-wave and U-wave abnormalities (blunting, notching, inversion); ST-segment depression; rightward axis of the terminal 40 msec of the QRS; atrioventricular, bundle-branch, fascicular, and intraventricular conduction disturbances; and supraventricular and ventricular tachyarrhythmias [3, 84–90]. These cardiac effects are observed most commonly with aliphatic and piperidine phenothiazines. Thioridazine is perhaps the most cardiotoxic agent. In one study of 299 patients with antipsychotic overdose, thioridazine had a significantly greater incidence of prolonged QT_c interval (60%), prolonged QRS interval (23%), and arrhythmia (5%) than chlorpromazine (34%, 15%, and 0%, respectively) and other antipsychotics (19%, 6%, and 0%, respectively) [3]. ECG changes and arrhythmias occasionally have been described after overdose of the newer atypical antipsychotics [66, 67, 91–96].

Repolarization abnormalities are the earliest and most common abnormalities noted on the ECG of patients with antipsychotic poisoning [84–86, 89]. Although observed with therapeutic doses, repolarization abnormalities are dose and concentration dependent and more prevalent in overdose. Prolongation of the QT interval has been observed with aliphatic and piperidine phenothiazines, droperidol, haloperidol, loxapine, pimozide, quetiapine, sertindole, risperidone, and ziprasidone [3, 42, 92, 94–102]. Therapeutic

doses of sertindole have been associated with a mean QT_c interval increase of 21 msec in one premarketing trial and a QT_c interval greater than 500 msec in 50% of patients in another trial [91, 103]. The manufacturer withdrew its new drug application in the United States due to fear of polymorphic ventricular tachycardia from this agent. Torsades de pointes has been described after overdose with droperidol, haloperidol, mesoridazine, pimozide, sertindole, and thioridazine [104]. This complication is particularly important to the intensivist who uses haloperidol to sedate agitated patients in the intensive care unit. In one study, torsades de pointes occurred in 3.6% of hospitalized critically ill patients who received intravenous haloperidol for sedation [141]. The incidence of torsades de pointes was increased significantly when greater than 35 mg of haloperidol was administered in less than 6 h (64%) and when the QT_c interval was greater than 500 msec (84%). No patient who had a QT_c interval less than 500 msec developed torsades de pointes.

Ventricular tachyarrhythmias may underlie sudden death that has been associated with therapeutic doses of phenothiazines [105–107]. Thioridazine is likely the most dangerous. In one case series of 49 deaths associated with therapeutic doses of antipsychotics, more than half of the cases were associated with thioridazine [106].

Seizures

Although all antipsychotics are considered to lower the seizure threshold and produce dose-related EEG abnormalities, seizures occur uncommonly [38, 39]. Generalized and partial seizures have been reported, but generalized major motor seizures predominate. Seizures are most likely to occur in patients with one or more risk factors, at higher therapeutic doses, and after overdose with certain agents (e.g., chlorpromazine, clozapine, loxapine) [38–42]. Risk factors for seizures include organic brain disease, epilepsy, a history of electroconvulsive therapy, abnormal baseline EEG, polypharmacy, large drug doses, and initiation or rapid dose escalation of antipsychotics [38,

41]. Seizures have been reported to occur in 2.4% of patients taking clozapine and 1.2% of patients taking phenothiazines [38, 40]. The incidence of seizures rises, however, to 4.4% for patients taking greater than 600 mg of clozapine daily and 9% for patients taking greater than 1 g of chlorpromazine daily [39, 40]. Seizures are unlikely to occur when certain traditional agents (e.g., fluphenazine, haloperidol, molindone, pimozide) and newer atypical agents are used; these agents have a seizure incidence comparable to placebo (<1%) during therapeutic dosing [38]. Overall the incidence of seizures is low after antipsychotic overdose. In one study of 299 patients with antipsychotic overdose, the incidence of seizure was only 1% [3]. For clozapine and loxapine, however, the risk is much higher. Seizures have occurred in 10% of clozapine overdoses reported in the literature [67]. There is an estimated 10% cumulative risk of seizure after 3.8 years of therapeutic use. The risk of seizures with clozapine appears to be dose dependent and is greatest with high-dose therapy (greater than 600 mg/day) [40]. In one series of ten patients with loxapine overdose, seizures occurred in 6 (60%) and were often multiple [42].

Hepatotoxicity

Asymptomatic elevations of hepatic transaminases have occurred during treatment with most antipsychotics [108, 109]. These abnormalities commonly are noted during the first 3 months of therapy and are self-limiting. The incidence is variable according to agent; incidences of 37%, 20%, and 16% have been described for clozapine, chlorpromazine, and haloperidol, respectively [108, 109]. Clinically significant hepatotoxicity occurs in a small proportion of patients. Hepatotoxic reactions are idiosyncratic and not observed with acute antipsychotic overdose. Chlorpromazine carries an incidence of overt liver disease of 0.1–1% [108, 110]. Cholestatic jaundice is the characteristic pattern of injury. In support of a hypersensitivity mechanism, the injury most often occurs within 1 month of therapy onset, is characterized by a rash and eosinophilia in most cases, and is not dose related [108, 111]. Cholestatic jaundice also has been

associated rarely with haloperidol and risperidone therapy. Chlorpromazine and clozapine also may cause direct hepatocyte cytotoxicity [108].

Blood Dyscrasias

Agranulocytosis (absolute neutrophil count $<500/\text{mm}^3$ [3]) is a life-threatening idiosyncratic reaction that rarely may occur with phenothiazine and clozapine therapy. It occurs in approximately 1 in 10,000 patients receiving chlorpromazine, usually within the first 8–12 weeks of treatment [112, 113]. The incidence is higher with clozapine (1–2%) and, as for chlorpromazine, usually occurs within the first 3 months of therapy [114, 115]. Mortality rates range from 30% to 85% when agranulocytosis occurs [115]. The risk of clozapine-associated agranulocytosis is minimized by weekly white blood cell count monitoring. With regular monitoring, the incidence (cumulative risk 0.8% at 1 year) of and mortality (4%) from agranulocytosis have been reduced [114, 115]. The mechanism of clozapine-associated agranulocytosis has not been determined but is likely to result from immune-mediated and direct drug-induced myelotoxicity [116]. Granulocyte colony-stimulating factor has shortened recovery time significantly when administered to patients with antipsychotic-associated granulocytopenia [117].

Extrapyramidal Syndromes

EPS are a group of sustained-movement disorders that occur in approximately 30% of patients treated with antipsychotics and often lead to medication noncompliance, inadequate treatment, and an exacerbation of the symptoms of schizophrenia [118]. New-generation atypical antipsychotics are associated with a significantly lower incidence and severity of EPS; rates not significantly different from placebo have been found with clozapine, olanzapine, quetiapine, and sertindole [10, 103, 119]. EPS may occur within hours to days (e.g., acute DRs, akathisia), days to months (e.g., akathisia, parkinsonism), or months to years

(e.g., TD) from the initiation of therapy and may be reversible or irreversible. The neuroleptic malignant syndrome, a severe EPS, rarely may occur during treatment and is discussed in the chapter devoted to that syndrome.

Acute DRs are reversible motor disturbances that occur soon after initiation of antipsychotic therapy or after an increase in dose. Of acute DRs, 50% occur within 48 h, and 90% occur within 5 days of antipsychotic treatment [120, 121]. Peak incidence occurs when antipsychotic concentrations are declining in the serum. Acute DRs are characterized by sustained muscle contractions resulting in abnormal posturing of the eyes, face, tongue, jaw, neck, back, abdomen, and pelvis. Clinical manifestations include facial grimacing, trismus, oculogyric crisis, blepharospasm, tongue protrusion, buccolingual dyskinesias, dysarthria, swallowing difficulties, retrocollis, torticollis, opisthotonos, tortipelvis, gait disturbance, and, rarely, stridor from laryngospasm. Impaired respiration caused by dystonia of laryngeal and pharyngeal muscles rarely may result in death [122]. Acute DRs are characterized by a patient who is awake and alert. The overall prevalence of acute DRs is approximately 2%, but the incidence varies according to individual susceptibility (presence of risk factors), agent identity, dose, and duration of therapy [118]. Patient-related risk factors include male sex, young age (5–45 years old), a personal or family history of acute dystonia, and recent alcohol or cocaine use [118–121, 142, 144]. High-potency D_2 -receptor antagonists cause acute DRs more frequently than do low-potency agents. Acute DRs have been reported to occur in 25% of patients treated with intramuscular fluphenazine, 16% of patients treated with haloperidol, 8% of patients taking thiothixene, 3.5% of patients taking chlorpromazine, and 1% or less of patients treated with atypical agents [10, 43, 119–121]. Clozapine is the only known atypical antipsychotic that does not induce acute dystonia. Although previously considered an idiosyncratic reaction, acute DRs are more likely to occur with larger drug doses and frequently have been described after acute antipsychotic overdose [66, 75–77].

Akathisia is the subjective sensation of motor restlessness that occurs within hours to days of the initiation of antipsychotic therapy [10, 119]. Akathisia is characterized by a compelling need to move and the inability to maintain a stable position or posture for several minutes. Patients may be irritable and anxious; have difficulty concentrating; and often constantly move their legs, rock, pace, or shift their weight from foot to foot. Vital signs are normal. Akathisia occurs in approximately 30% of patients taking antipsychotics [10, 119]. In one study, akathisia developed in 44% of patients within 1 h after taking a single 10-mg intravenous dose of prochlorperazine [123]. Akathisia occurs more commonly in women and is more prevalent with high-potency antipsychotics.

Parkinsonism is a reversible, intermediate-stage extrapyramidal syndrome that often occurs 5–30 days after starting antipsychotic therapy [10, 119]. In a study of 1559 patients treated with antipsychotics, parkinsonism was noted in 66% of patients [118]. Parkinsonism is characterized by bradykinesia (slow movement) or akinesia, masked facies, muscular rigidity (e.g., cogwheeling), tremor (e.g., pill rolling), gait and postural instability, bradyphrenia (slow thinking), and cognitive impairment. The risk of drug-induced parkinsonism is greatest in the elderly, patients with organic brain injury, patients taking high-potency agents, and patients receiving long-term antipsychotic therapy [118].

TD is a late-appearing, potentially irreversible movement disorder that occurs in approximately 20% of patients who receive long-term antipsychotic treatment and 50% of high-risk individuals (e.g., the elderly) [10, 119]. With conventional antipsychotic therapy, an annual incidence of 3–5% for TD has been reported. Atypical antipsychotics have a lower propensity to cause TD, with an annual incidence of less than 2% [10, 119]. It has been associated with all antipsychotics except clozapine. TD is characterized by stereotyped, involuntary, repetitive, painless movements of the face, eyelids, mouth, tongue, extremities, or trunk. Clinically, patients show chewing, tongue protrusion, lip smacking and puckering, rapid eye blinking, facial

grimacing, grunting, and, occasionally, slow choreoathetosis of the arms and legs. Orofacial movements are the earliest and most frequent clinical manifestations. The risk of developing TD is greatest in the elderly, patients with organic brain injury, patients taking high-potency agents, and patients receiving long-term antipsychotic therapy [124].

Diagnosis

The diagnosis of antipsychotic poisoning is based on a history of ingestion; suggestive physical findings; and corroborating evidence from ECG, laboratory, and other adjunctive tests. A history that suggests poisoning includes report of antipsychotic exposure by the patient or an acquaintance, a medication list that includes an antipsychotic, known history of psychosis or treatment with an antipsychotic, and the discovery of an antipsychotic near the patient before or on hospital arrival. The presence of CNS or respiratory depression, anticholinergic stigmata (see ► Chap. 23, “Anticholinergic Syndrome”), miosis, sinus tachycardia, hypotension, and EPS on physical examination suggests antipsychotic poisoning. An ECG that shows repolarization abnormalities (e.g., nonspecific ST-T changes, QT interval prolongation) with or without sinus tachycardia is consistent with antipsychotic exposure. An abdominal radiograph may show radiopaque densities with phenothiazine and butyrophenone poisoning. The absence of this finding, however, does not rule out poisoning with these agents. Chlorpromazine, mesoridazine, quetiapine, and thioridazine often produce false-positive results for tricyclic antidepressants on immunoassay screens. When necessary, toxicological screening by gas chromatography–mass spectrometry or high-performance liquid chromatography may be used to confirm the presence of some antipsychotics. Quantitative drug concentrations may be obtained but are not helpful in guiding therapy; they generally are not available in a timely manner and do not correlate well with clinical toxicity [49, 50, 52].

Differential Diagnosis

Poisoning by antipsychotics may mimic the neurological and cardiovascular effects produced by alcohols, antiarrhythmics, anticholinergics, antiepileptics, antihistamines, barbiturates, cyclic antidepressants, opiates, and sedative-hypnotics. Specifically, mesoridazine and thioridazine toxicity may be clinically indistinguishable from that produced by tricyclic antidepressants. CNS infection, occult trauma, cerebrovascular accident, and metabolic abnormalities always should be considered in the differential diagnosis and ruled out by appropriate testing. Acute dystonic reactions must be differentiated from alkalosis/hypocarbica; anticholinergic, antiepileptic, and strychnine poisoning; cerebrovascular accident; CNS and oropharyngeal infections; conversion disorder; hypocalcemia; hypomagnesemia; and joint dislocations. In addition, numerous drugs other than antipsychotics may produce acute DRs. Akathisia often may be misinterpreted as acute anxiety or agitation. Parkinsonism produced by antipsychotics may be indistinguishable from that produced by cerebrovascular accidents; CNS infection and trauma; and poisoning by carbon disulfide, carbon monoxide, cyanide, manganese, methanol, metoclopramide, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), and reserpine.

Treatment

Overdose

Treatment for antipsychotic overdose is primarily supportive. Endotracheal intubation and assisted ventilation should be instituted for patients with significant CNS or respiratory depression. All patients should have an intravenous line established, an ECG performed, and continuous monitoring of cardiac and respiratory function. Serum glucose measurement and administration of naloxone, oxygen, or thiamine should be considered in patients with coma or seizures. Patients with mild-to-moderate CNS depression who do not initially require endotracheal intubation should be placed in the lateral decubitus, head-

down position to minimize the risk of aspiration (III). Arterial blood gas; urinalysis; and measurements of serum creatine phosphokinase, calcium, and magnesium additionally should be obtained for patients with seizures, hyperthermia, or severe toxicity. A complete blood count should be obtained for any patient who presents with fever while taking clozapine or chlorpromazine. Serial evaluations of mental status and vital signs are important to determine the course of poisoning and the need for further testing and intervention.

Hypotension should be treated initially with Trendelenburg's position and rapid intravenous crystalloid infusion (i.e., 10–40 mL/kg normal saline or lactated Ringer's solution). Refractory hypotension should be treated with inotropes or vasopressors. Preferred first-line vasopressors include either norepinephrine or epinephrine infusions, whose direct alpha-adrenergic agonist effects can overcome the alpha-adrenergic antagonist effects of many antipsychotics (III). Central venous and peripheral arterial monitoring may be needed for patients who require significant doses of pressors to maintain perfusion.

Indications for ICU Admission in Antipsychotic Poisoning

Significant central nervous system depression (unresponsive to verbal stimuli)

Significant central nervous system agitation (requiring chemical or physical restraint)

Respiratory depression ($PCO_2 > 45$ mmHg)

Hypoxia or respiratory failure (adult respiratory distress syndrome)

Need for endotracheal intubation

Hypotension (systolic blood pressure ≤ 80 mmHg) not immediately responsive to crystalloid

Multiple seizures with altered mental status

Nonsinus cardiac rhythm

Acute overdose with $QRS > 120$ msec or $QT_c > 500$ msec

Second-degree or third-degree atrioventricular block associated with poisoning

(continued)

Need for invasive hemodynamic monitoring (e.g., pulmonary artery catheter, arterial line)

Extremes of temperature (e.g., $\geq 40^{\circ}\text{C}$ or $\leq 32^{\circ}\text{C}$)

Significant acid–base or metabolic disturbances requiring close monitoring or aggressive correction

Initial diagnosis of neuroleptic malignant syndrome

Adapted from Brett et al. [125].

Sinus tachycardia does not require specific treatment. Supraventricular tachycardias may be treated according to standard advanced cardiac life-support guidelines. Ventricular tachyarrhythmias may be treated with standard doses of lidocaine and electrical cardioversion, depending on the hemodynamic stability of the patient. Sodium bicarbonate (1–2 mEq/L intravenous boluses) is indicated as first-line therapy for ventricular or wide-complex tachycardias associated with mesoridazine, thioridazine, and, rarely, other agents (III). Type IA (e.g., procainamide), type IC (e.g., propafenone), and type III (e.g., amiodarone) antiarrhythmic agents are not recommended and are potentially dangerous; these agents may impair cardiac conduction further. Torsades de pointes should be treated by standard methods (see ► Chap. 21, “Cardiac Conduction and Rate Disturbances”) [126–129].

Seizures generally are treated best with benzodiazepines (e.g., diazepam, lorazepam) followed by barbiturates (e.g., phenobarbital), as necessary. The efficacy and safety of phenytoin has not been established for antipsychotic-associated seizures and is not recommended (see ► Chap. 20, “Toxicant-Induced Seizures” for a fuller discussion of this point). Patients with recurrent seizures (e.g., loxapine poisoning) rarely may require neuromuscular paralysis and endotracheal intubation to prevent rhabdomyolysis and myoglobinuric renal failure. Continuous EEG monitoring is required for these patients to determine the efficacy of antiepileptic therapy (see ► Chap. 20, “Toxicant-Induced Seizures”).

Physostigmine may be used to control agitation and reverse delirium in patients who have

significant anticholinergic toxicity (II-3). Its duration of action is less than 1 h, however, so repeat dosing may be necessary. Physostigmine is generally safe. Caution has been suggested if the ECG shows cardiac conduction delays; [130] however, this should not be considered an absolute contraindication. It has been used successfully to reverse the anticholinergic syndrome associated with chlorpromazine, clozapine, olanzapine, and thioridazine [130, 131]. Physostigmine should be given slowly intravenously (0.02 mg/kg in children or 2 mg in adults) over 2 min (see ► Chap. 161, “Physostigmine” for a full discussion of the clinical pharmacology of this antidote). Physostigmine-treated patients should be observed closely for at least 15 min for evidence of cholinergic excess. Alternatively, agitated behavior associated with the anticholinergic effects of antipsychotics may be treated with benzodiazepines. Of note, the anticholinergic effects of these agents manifest early and can be prolonged. Patients may demonstrate anticholinergic delirium when they emerge from coma following resolution or other neuroreceptor effects that potentiated early coma in the overdose patient.

Activated charcoal adsorbs antipsychotic agents effectively; however, its efficacy in altering the clinical course or outcome in these patients is unknown. Because patients ingesting these agents may develop a decrease in mental status or seizures, activated charcoal should be used cautiously, if at all. It is unlikely to alter drug absorption if given after an hour post ingestion. Gastric lavage is not recommended (see ► Chap. 3, “Therapeutic Approach to the Critically Poisoned Patient”). Multiple-dose activated charcoal has no proven clinical benefit for antipsychotic poisoning and is not recommended. Because antipsychotics have large volumes of distribution, have high protein binding, and are metabolized predominantly in the liver, their elimination is not enhanced by hemodialysis, hemoperfusion, forced diuresis, or urinary alkalinization techniques [132–134]. Urinary alkalinization is reserved for patients with rhabdomyolysis that may result from antipsychotic-associated seizures or hyperthermia.

Acute Dystonic Reactions

Treatment of acute dystonic reactions (DRs) may rarely require supplemental oxygen and assisted ventilation for patients with respiratory distress from laryngeal and pharyngeal dystonia. Pharmacological therapy with a parenteral anticholinergic dopaminergic (antiparkinsonian) agent is highly effective and usually provides relief within 10 min of administration [143]. Benztropine, which is a potent inhibitor of dopamine uptake (0.02–0.05 mg/kg) or diphenhydramine (1 mg/kg), may be given intramuscularly or slowly intravenously over 2 min. Repeat dosing may be necessary for complete resolution of acute DRs. Resistant cases may respond to diazepam (0.1 mg/kg intravenously) or lorazepam (0.05–0.1 mg/kg intravenously). A search for other underlying illnesses should be sought whenever acute DRs are resistant to antiparkinsonian treatment. After parenteral therapy, an oral antiparkinsonian agent should be administered for 48–72 h to prevent acute DR recurrence [135]. When continued antipsychotic therapy is necessary, patients also should be maintained on an antiparkinsonian agent or switched to an antipsychotic with lower EPS liability [119].

Akathisia

Although recommended as initial therapy, anticholinergic/antiparkinsonian agents often are ineffective for the treatment of akathisia [119]. These agents seem to be effective, however, when administered prophylactically. Pretreatment with diphenhydramine significantly decreases the incidence of akathisia that follows a single therapeutic dose of prochlorperazine [136]. Treatment with a benzodiazepine, propranolol (20 mg orally twice daily), or clonidine (0.1 mg orally three times daily) may be beneficial [137, 138]. When continued antipsychotic therapy is necessary, akathisia may be minimized by reducing the antipsychotic dose, adding an anticholinergic agent, or switching to an antipsychotic with lower EPS liability [119].

Parkinsonism

Parkinsonism effects may be minimized by using low doses of traditional antipsychotics, switching to an atypical agent, or adding an anticholinergic/antiparkinsonian agent (e.g., benztropine, biperiden, diphenhydramine, or trihexyphenidyl) or an agent that enhances dopaminergic activity (e.g., amantadine) [119].

Tardive Dyskinesia

Tardive dyskinesia (TD) is often irreversible and has no consistently effective treatment. The best treatment for TD is to minimize its risk of occurrence. The best preventive practice is to use the minimal effective dose of an antipsychotic for long-term therapy and to discontinue treatment when it is no longer medically necessary [119]. An alternative option is to treat patients with atypical agents, which have a lower propensity to induce TD with long-term treatment. Some atypical agents are antidyskinetic (e.g., clozapine, olanzapine, quetiapine, risperidone); the severity of TD is reduced after a change in regimen to these agents from a traditional antipsychotic [119].

Disposition

For all antipsychotics, signs and symptoms develop rapidly (within 4 h) after acute ingestion. After an initial treatment and observation period in the emergency department, clinical reassessment can reliably identify patients who are at high risk for complications and require intensive care and patients who may be medically discharged. Most patients with pure antipsychotic overdose develop only mild toxicity and are medically safe for psychiatric evaluation and disposition after an observation period of 4–6 h in the emergency department. Patients who manifest persistent mild toxicity (e.g., ataxia, lethargy, sinus tachycardia, repolarization abnormalities on ECG) should be admitted to a monitored bed for continued observation. Patients with moderate

to severe toxicity (e.g., moderate-to-severe CNS or respiratory depression, hypotension, seizures, marked agitation, acid–base disturbances, arrhythmias other than mild sinus tachycardia, and cardiac conduction disturbances) should be admitted to an intensive care unit for aggressive supportive care. Admission to a monitored bed also is recommended for patients who take phenothiazines on a long-term basis and have incidental ECG abnormalities (e.g., prolonged QRS or QT_c intervals); these patients are considered at risk for sudden phenothiazine death. When the appropriate disposition of a patient is in question, consultation with a medical toxicologist or poison control center is recommended.

Special Populations

Patients with Renal Impairment

Because most antipsychotics are metabolized extensively in the liver before excretion, they are not affected significantly by changes in renal function. Normally, small amounts (1–3%) of a parent drug are excreted unchanged by the kidney [49]. Aside from the benzamide derivatives (e.g., remoxipride, sulpiride, and risperidone), these drugs commonly do not require dose alteration for patients with renal impairment [50]. Even when clearance is prolonged due to renal dysfunction, clinical toxicity is unlikely to be lengthened appreciably after overdose in this patient population.

Patients with Hepatic Impairment

Most patients with hepatic disease (e.g., cirrhosis, hepatitis) and conditions that decrease hepatic blood flow (e.g., congestive heart failure) have decreased antipsychotic clearance from plasma and require dose adjustment with long-term therapy [50]. After acute overdose, antipsychotic clearance may be prolonged but is unlikely to delay clinical recovery significantly.

Infants, Children, and Elderly Patients

Compared with normal adults, fetuses, infants, and elderly patients have a diminished capacity to metabolize and eliminate antipsychotics [6]. Children commonly metabolize these drugs more rapidly than adults. Compared with normal adults, plasma clearances of antipsychotics are reduced by 30–50% (elimination half-lives doubled) in the elderly [49, 50]. In general, elderly individuals are more sensitive than young adults to the effects of antipsychotics; they have decreased CNS, hepatic, renal, and cardiac function and have a greater tendency to develop anticholinergic stigmata, EPS (e.g., parkinsonism, TD), sedation, confusion, cardiac conduction abnormalities, and postural hypotension from these agents. Elderly patients ≥ 65 years old treated with antipsychotic agents for dementia-related psychosis are at greater risk for sudden death. The United States Food and Drug Administration has issued a black box warning for all antipsychotic agents used in this patient population. The relative risk of mortality with atypical antipsychotics is 1.6–1.7 times as compared to placebo; the relative mortality risk is even higher with traditional antipsychotic agent use [139, 140].

The safety and efficacy of most antipsychotics have not been established in pediatric patients. Similar to elderly patients, children may be more sensitive than normal adults to the CNS and respiratory depressant effects of these drugs. In addition, children are more likely to develop an acute DR than other age-groups.

Patients of Different Races and Ethnic Groups

Genetic polymorphisms of hepatic CYP isoenzymes often are associated with race or ethnic group variations. These polymorphisms result in large interindividual differences in antipsychotic steady-state plasma concentrations and clearance [51]. CYP isoenzyme differences become clinically important with long-term dosing or when

other CYP isoenzyme substrates are ingested concomitantly. Genetic polymorphisms of CYP2D6 may result in different concentrations of aripiprazole and thioridazine despite similar therapeutic doses in otherwise similar individuals [51]. Poor metabolizers at CYP2D6 are at greater risk for cardiovascular side effects from thioridazine and its metabolite mesoridazine. These individuals attain much higher plasma concentrations of unchanged thioridazine and the cardioactive ring sulfoxide metabolite [52]. The latter metabolite is CYP2D6 independent and preferentially formed when CYP2D6 activity is low.

Pregnant and Breast-Feeding Patients

There are no adequate, well-controlled studies in pregnant women that establish the safety of antipsychotics for the developing fetus. Most antipsychotics should be used during pregnancy only if the benefit justifies the potential risk to the fetus. Because most antipsychotics are secreted in breast milk and their safety to infants is not established, breast-feeding is not recommended for women taking antipsychotics.

Key Points in Antipsychotic Poisoning

1. Toxic effects are often an exaggeration of pharmacological effects.
2. For all antipsychotics, clinical effects occur rapidly (within a few hours) of acute ingestion.
3. The presence of central nervous system and respiratory depression, anticholinergic toxicity, miosis, sinus tachycardia, hypotension, and extrapyramidal side effects on physical examination should suggest antipsychotic poisoning.
4. Timely supportive care should prevent death in most patients with antipsychotic poisoning.
5. An electrocardiogram should be obtained for all symptomatic patients with

antipsychotic poisoning and cardiac monitoring instituted.

6. After an acute antipsychotic overdose, patients may be medically discharged if they remain asymptomatic after an observation period of 4–6 h; symptomatic patients should be observed until they are alert and electrocardiogram abnormalities resolve.

Prescription anxiolytic/sedative-hypnotic (ASH) drug toxicity, and withdrawal, is commonly encountered by health care providers in many clinical settings. Although the pharmacokinetic and epidemiologic characteristics of the agents involved have changed over several decades, the essential features of ASH poisoning (and withdrawal) remain unchanged since the introduction of chloral hydrate (CH) in the mid-nineteenth century. Today, ASH drugs are ubiquitous and used for numerous indications by inducing anxiolysis and sedation that result in drowsiness or sleep. Overall, this drug group consists of benzodiazepine (e.g., diazepam) and benzodiazepine-like drugs (e.g., zolpidem), barbiturate (e.g., butalbital) and barbiturate-like drugs (e.g., meprobamate), and drugs (e.g., dexmedetomidine) with different mechanisms of action. The toxic effects of barbiturates are discussed in detail in another chapter (► Chap. 46, “Barbiturates”). Other agents, such as dexmedetomidine, are discussed in greater detail elsewhere (see ► Chap. 35, “Alpha-2 Adrenergic and Imidazoline Receptor Agonists: Clonidine, Dexmedetomidine, and Related Antihypertensives, Decongestants, and Sedatives”).

Prescription drugs with ASH activity possess significant abuse potential. The objectives of intentional misuse include achievement of a euphoric state, attenuation of undesirable side-effects of other drugs (e.g., methamphetamines), relief of withdrawal symptoms, and criminal acts (e.g., sexual assault) after surreptitious administration. Evidence is gathering that ASH agents, particularly when co-prescribed with opioid analgesics, convey greater risk of death compared to population matched controls [1, 2]. As a result of the

development of pharmacodynamic tolerance, chronic abuse of these agents causes a characteristic withdrawal syndrome after abrupt discontinuation. The resulting effects are very similar to the withdrawal syndrome associated with ethanol (see ► Chap. 27, “Withdrawal Syndromes”).

Benzodiazepines are one of the most widely prescribed class of drugs worldwide. Many other prescription ASH, including chloral hydrate (‘Mickey Finn’), glutethimide (Doriden®), (Current and past trade names of these agents as marketed in the United States are given. These may be different in other countries) ethchlorvynol (Placidyl®), and methaqualone (Quaalude®) are historically important sources of abuse and poisoning. There has been a marked decline in the reported exposures to these older agents in the United States from 7.5% to <1% of the ASH category over 30 years [3, 4]. However, some of these medications remain available in non-US markets and, because of their limited use, are briefly summarized in this chapter.

Biochemistry and Clinical Pharmacology of Benzodiazepines

The structures of representative sedative-hypnotic drugs are shown in Fig. 1. Except for clorazepate, whose bioavailability requires gastric decarboxylation to nordiazepam, benzodiazepines are well absorbed following oral administration [5]. Other relevant pharmacokinetic properties of benzodiazepines, including a high degree of protein binding (60–95%), are summarized in Table 1. The

Table 1 Benzodiazepines and Benzodiazepine-like drugs

Generic drug (trade name)	Estimated equivalency (mg)	Half-life parent compound (hr)	Estimated duration (hr) ^a
Onset: 2–3 h			
Halazepam (Paxipam)	20	14–15	Long ^b
Oxazepam (Serax)	20	3–25	Intermediate
Prazepam (Centrax)	20	Prodrug	Long ^b
Temazepam (Restoril)	15	5–20	Intermediate
Zolpidem (Ambien)	10	1.4–4.5	Short
Onset: 1–2 h			
Alprazolam (Xanax)	0.75	6.3–26.9	Intermediate
Chlordiazepoxide (Librium*)	25	5–48	Long ^b
Clonazepam (Klonopin)	2	18–50	Long ^b
Estazolam (ProSom)	2	10–34.6	Intermediate
Flurazepam (Dalmane)	15	Prodrug	Long ^b
Lorazepam (Ativan)	1	10–20	Intermediate
Quazepam (Doral)	15	25–53	Long ^b
Triazolam (Halcion)	0.375	1.5–5.5	Short
Onset: <1 h			
Clorazepate (Tranxene)	15	Prodrug	Long ^b
Diazepam (Valium)	10	20–80	Long ^b
Midazolam (Versed)	0.035	1.5–12	Intermediate
Flunitrazepam (Rohypnol)	1	10–30	Intermediate

^aArbitrarily based on mean half-life of parent compound: half-life <4 h = short; half-life ≤24 h = intermediate; half-life >24 h = long duration

^bDue to presence of active metabolite with a long half-life

Fig. 2 Metabolism of selected benzodiazepines
(From Rech [127])

related metabolic pathways of select benzodiazepines are shown in Fig. 2.

Unless occurring in combination with other central nervous system (CNS) depressants, benzodiazepine overdose, even in large amounts, rarely results in life-threatening respiratory or hemodynamic manifestations. The wide margin of safety of benzodiazepines has made them appealing for the management of anxiety disorders, agitation, and substance abuse and withdrawal. Relatively newer additions to the market (zolpidem, zalepon and eszopiclone) also mediate their effects through CNS benzodiazepine receptors [6]. Their clinical pharmacology and toxicology are similar to those of benzodiazepine drugs.

Benzodiazepines primarily undergo hepatic metabolism with some drugs (e.g., chlordiazepoxide and diazepam) having active metabolites with slower elimination than their parent compound. Pre-existing liver disease or concurrent use of agents that inhibit hepatic metabolism (e.g., CYP3A4 inhibitors, such as selected macrolide antibiotics) may result in prolonged clinical effects.

Pathophysiology of Toxic Effects

The sedative and anticonvulsant effects of benzodiazepine (like) drugs result from activity on two CNS inhibitory neurotransmitters. Agonism of γ -aminobutyric acid (GABA) neuronal receptors enhances the binding of GABA to postsynaptic chloride (GABA_A) channels (Fig. 3). Benzodiazepine compounds also inhibit the presynaptic uptake of adenosine, which exerts a negative modulatory effect on the presynaptic release of glutamate, an excitatory neurotransmitter in the CNS [7]. These actions result in an increased postsynaptic influx of negatively charged ions (Cl^-), and decreased glutamate-stimulated postsynaptic influx of positively charged ions (Na^+ and Ca^{2+}). The end effect is widespread postsynaptic neuronal hyperpolarization and suppression of electrical impulse propagation.

Clinical Presentation and Life-Threatening Complications

The clinical manifestations of acute and chronic benzodiazepine overdose range from mildly depressed sensorium to coma. Impaired psychomotor skill, somnolence, dysarthria, nystagmus, ataxia, hyporeflexia, and respiratory depression are common features of intoxication [5, 8]. In general, the severity and duration of these effects increase with age, which is explained on the basis of age-related changes in drug disposition and neuropharmacologic actions (see ► Chap. 8, “Geriatric Poisoning”). If respiratory failure occurs, it suggests the presence of another CNS depressant agent or underlying disease (e.g., chronic obstructive pulmonary disease).

Retrograde and anterograde amnesia occur after therapeutic and supratherapeutic doses of benzodiazepines, which are advantageous during uncomfortable medical procedures. The acute ingestion of benzodiazepines will raise the seizure threshold and offer prophylactic anticonvulsant effects, particularly after an overdose involving a proconvulsant agent (e.g., bupropion).

Anxiolytic/Sedative-Hypnotic Drug Withdrawal

Long-term administration of any ASH (or GABA-agonist) medication may result in pharmacodynamic tolerance and a potentially life-threatening withdrawal syndrome if the agent(s) is abruptly stopped. Tolerance to these agents is due to the down-regulation of neuroinhibitory cell membrane receptor expression or functional activity [9]. The abrupt cessation triggers a sudden imbalance in CNS excitatory neurotransmission. The clinical result of this CNS hyperactivity is similar with most of these agents except in terms of the timing of onset (based on the half-life of the involved drug) and intensity (based on the amount used on a regular basis).

The temporal course of ASH withdrawal depends on the elimination rate of the parent

Fig. 3 Idealized model of γ -aminobutyric acid (GABA)-benzodiazepine (BZ)-chloride (Cl^-) channel at axosomatic (postsynaptic) inhibitory synapses. **a** Presynaptic and postsynaptic elements. *ap* action potential, *Gad* glutamic acid decarboxylase, *EC* extracellular, *IC* intracellular, *ipsp* inhibitory postsynaptic potential. **b** GABA-BZ receptor interactions influencing permeability of chloride channels.

Neutral: GABA receptor binds GABA (G) with moderate affinity in the absence of BZ ligand. BZ agonist: Direct BZ agonist (B) enhances GABA affinity for its receptor, resulting in maximal chloride permeability. Inverse agonist: Inverse agonist bound to BZ receptor results in poor GABA affinity and markedly reduced chloride permeability (From Rech [127])

drug involved and whether it is metabolized to active compounds. These metabolites may have longer half-lives (e.g., desmethyldiazepam, half-life ~100 h; diazepam, half-life ~45 h). Withdrawal begins more rapidly with compounds having shorter elimination rates. Following an abrupt stoppage of use, withdrawal starts within 24 h for short-acting benzodiazepines, 24–36 h for carisoprodol/meprobamate, and 4–8 days for long-acting benzodiazepine compounds.

In contrast to the relatively more benign clinical effects of opioid withdrawal, acute withdrawal from sedative-hypnotic agents can be life-

threatening. Symptoms and signs of withdrawal range from relatively minor (e.g., restlessness, tremor, and insomnia), to more severe (e.g., agitated delirium, psychosis, hyperthermia, tachyarrhythmias, and seizures) [10]. Hypertension, tachypnea, mydriasis, and diaphoresis are commonly seen but also occur in withdrawal for any GABA-agonist agent.

A complete differential diagnosis for ASH withdrawal includes both toxicological and non-toxicological diseases that may be indistinguishable from one another based on presenting clinical features. This differential includes

sympathomimetic (e.g., amphetamines) and methylxanthine (e.g., caffeine) toxicity; thyrotoxicosis; hypoglycemia; and neurosepsis. Anticholinergic poisoning, with the exception of anhidrosis and specific neurobehavioral features (e.g., mumbling speech and carphologia; see ► Chap. 23, “Anticholinergic Syndrome”), also presents with similar features.

Special Agents

Dexmedetomidine

Dexmedetomidine (DXM) is a centrally acting α_2 agonist which decreases release of catecholamines resulting in sedation and, at higher doses, bradycardia and hypotension; it may also have mild analgesic properties [11, 12]. It has been successfully used for pediatric sedation via oral and intranasal administration [13, 14]. Dexmedetomidine is indicated for short term weaning of mechanical ventilation, but has been used for procedural sedation and as an adjunct for GABA-agonist withdrawal [15, 16]. However, while it does assist in controlling signs of GABA withdrawal’s hyperadrenergic state it does little to prevent seizures and should not be used as a sole agent [16]. Its volume of distribution in healthy volunteers is <1 L/kg but can be larger in critically ill patients [17]. The terminal half-life is approximately 1.8 h, and an infusion rate of 0.7 $\mu\text{g/kg/h}$ will maintain steady state concentrations in most patients [18]. Although it causes less respiratory depression than other sedative agents, at higher doses the most common side effects are bradycardia and hypotension [19]. Treatment of these effects includes stopping the infusion and supportive care.

Propofol

Propofol is a GABA_A agonist and NMDA antagonist that, at high concentrations, can directly open chloride channels. It also results in minor dopamine release from nigral pathways and

possible dopamine agonism at D2 receptors. It is unclear, however, if these effects are clinically significant in humans. Propofol is used for induction of anesthesia and is now one of the most commonly used parenteral anesthetics. It is also used for sedation of ventilated patients, procedural sedation and treatment of status epilepticus. Sedative effects are achieved within seconds after administration and rapidly resolves (after discontinuation) after use of short periods of time. The intravenous induction dose is around 2 mg/kg and an infusion of 0.2 mg/kg/min will usually maintain anesthesia. Sedating doses of propofol may result in myocardial depression, hypotension and respiratory depression. Propofol is formulated in a soybean oil emulsion which can support bacterial growth if not used promptly after opening.

Higher doses of propofol, typically infused for longer than 48 h, may result in a propofol infusion syndrome. This syndrome includes cardiovascular instability, metabolic acidosis, rhabdomyolysis and renal insufficiency. Prolonged sedation after termination of the infusion and deaths have been reported.

Ramelteon

Ramelteon, a newer sedative agent, is an agonist at melatonin (MT1 and MT2) receptors. These are G protein-linked receptors primarily in the suprachiasmatic nucleus. Agonism at these receptors increases sleep length and decreases sleep latency [20]. The therapeutic half-life is about 1.5 h [21]. Limited data on clinical effects report fatigue, CNS depression, dizziness and headache [22]. Episodes of sleep-walking (and other parasomnias) are possible; a withdrawal syndrome has not been reported.

Suvorexant

Suvorexant, another newer medication, antagonizes orexin receptors. Sleep-wake cycle signals originate in the lateral hypothalamus and then project into several brain nuclei where orexin receptors are located. By antagonizing these

Fig. 4 Metabolism of chloral hydrate (CH). TCAA trichloroacetic acid, TCE trichloroethanol

receptors, signals for wakefulness are inhibited [23]. Reported adverse effects in therapeutic dosing include hallucinations, somnolence, headache, abnormal dreams and dizziness [24, 25].

Chloral Hydrate

Chloral hydrate was introduced into clinical medicine by Liebreich in 1869 and, shortly thereafter, used maliciously by adding it to alcoholic drinks and being referred to as a “Mickey Finns” or “knockout drop.” CH is available as a liquid, capsule, or rectal suppository. The recommended and most commonly reported doses used for pediatric outpatient sedation range from 25 to 100 mg/kg [26]. There has been much work published on the use of CH for procedural sedation, with mixed results and recommendations [27]. Several recent studies have shown CH to be safe [28–30]. There are, however, rare reports of death following CH-induced sedation [31, 32]. Newer, more predictable sedative agents should increasingly take the place of CH in clinical medicine [31].

After complete absorption from the gastrointestinal (GI) tract, CH is metabolized rapidly in the liver, brain, and red blood cells to trichloroethanol (TCE) and trichloroacetic acid (TCAA) [33–35]. Rapid nicotinamide adenine dinucleotide (NADH)-dependent enzymatic reduction of

CH by alcohol dehydrogenase (ADH) produces the active metabolite TCE, which has two fates: hepatic glucuronidation to urochlorallic acid with subsequent renal (major) and bile (minor) excretion, or oxidation to TCAA (Fig. 4) [36–38].

The coadministration of ethanol, with CH, competitively inhibits the metabolism of TCE and (via its metabolism by ADH) results in a changed redox potential and net increase in the NADH-to-NAD ratio, which effectively drives primary CH metabolism to TCE (Fig. 5) [35, 39, 40]. Simultaneous increase in TCE production and its reduced metabolism result in a rapid development of peak plasma concentrations of TCE, which, combined with TCE-mediated inhibition of ethanol metabolism through ADH, are thought to explain the rapid and profound onset of CNS depression that are characteristic of a ‘Mickey Finn.’

Because the hepatic enzymatic elimination of CH in normal healthy adults and older children is rapid (half-life 4 min), the rate of detection of the parent compound in urine in most clinical situations is low, limiting the utility of toxicologic assay for the parent compound itself. [37, 42] The relatively more prolonged hypnotic effects of CH are attributed to the active metabolite TCE (half-life >6 h) [37, 42, 43]. With concurrent ethanol administration or after CH overdose, the elimination half-life of TCE reportedly has increased to greater than 30 h [44].

Fig. 5 Metabolic interaction of ethanol and chloral hydrate. *NAD* nicotinamide adenine dinucleotide, *NADH* nicotinamide adenine dinucleotide, reduced form; *TCE* trichloroethanol

The precise mechanism of action for CH is unknown. Several lines of evidence, including the demonstration of CH's rapid bioconversion, suggest that the dose-dependent hypnotic and sedating effects of CH are due in large part to its active metabolite, TCE [41–43, 45]. In addition, there is evidence to support TCE's indirect agonist actions at GABA_A chloride channels in a manner similar to that of barbiturates [46, 47]. Several mechanisms of CH-induced myocardial toxicity have been postulated, including sensitization of the myocardium to the dysrhythmogenic effects of catecholamines (similar to other halogenated hydrocarbons); reduction in myocardial contractility; and shortening of the refractory period of the myocardial action potential [37, 48, 49].

Mild sedation (drowsiness) occurs at low CH doses (250 mg in adults; 8 mg/kg in children), with hypnotic responses seen at moderate doses (500–1,000 mg in adults; 25–50 mg/kg in children). At therapeutic doses of CH, there is minimal depression of cardiovascular and respiratory function with maintenance of intact airway reflexes. Higher doses (>50 mg/kg in children) may produce more profound depression of respiratory and vasomotor functions. These effects develop within 1 h of oral or rectal administration.

Physiologic tolerance after long-term administration of CH has been in rare cases and is plausible based on its effects on GABA transmission [50, 51]. There is minimal risk for withdrawal following limited use for medical procedures [52].

The acute lethal dose of CH is variable, with death reported after ingestion of 4 g in one case and survival reported after ingestion of 30 g in another [53]. Although excessive depression in level of consciousness and attendant respiratory compromise are the most commonly occurring and anticipated toxic effects of CH overdose, most deaths reported after CH overdose usually occurred after development of cardiovascular shock and malignant cardiac dysrhythmias [54–57].

Reported dysrhythmias include premature ventricular beats, ventricular tachycardia, ventricular fibrillation, bigeminy, accelerated junctional rhythm, torsades de pointes, and asystole. Severe irritant GI injuries have been reported, including upper GI hemorrhage, perforation, and esophagitis with stricture formation [54, 58–62]. A case series involving accidental intravenous administration of CH with skin sloughing and cyanosis illustrates the soft tissue effects of direct exposure [63].

Chloral hydrate has been associated with hypersensitivity reactions as well as "DRESS" (drug reaction with eosinophilia and systemic symptoms) [64, 65]. The coadministration of CH and furosemide has been associated with adverse events, including hot flashes, diaphoresis, nausea, tachycardia, and alterations in blood pressure (hypertension and hypotension) [66, 67]. Typically, these clinical manifestations have been encountered shortly after intravenous furosemide

Fig. 6 Chemical structures of older sedative-hypnotic agents **a** Glutethimide, **b** Ethchlorvynol, **c** Meprobamate, **d** Methaqualone

administration in patients who had previously received CH. A toxicologic mechanism for these occurrences has not been established. Case reports suggest that these effects do not occur when furosemide is administered more than 24 h after the last dose of CH. A retrospective study documented the occurrence of transient (<20 min) flushing-type reactions in 3 of 43 patients (7%) who received intravenous furosemide after CH [68]. There is also a case report of an adverse drug interaction involving CH and methotrexate [69].

Older, Less Used Sedative-Hypnotics

Glutethimide, ethchlorvynol, meprobamate, and methaqualone (Fig. 6) are sedative-hypnotic drugs that have fallen out of common use, having been replaced largely by benzodiazepine and benzodiazepine-like drugs. For example, only one of these, meprobamate, is still available on the U.S. Food and Drug Administration (FDA) regulated pharmaceutical market and only as a U.S. Drug Enforcement Agency (DEA) schedule III (some abuse potential, but not as much as a schedule 1 or 2 drug, and low to moderate

likelihood of dependence) drug. Meprobamate is the major active metabolite of a widely prescribed, non-DEA-scheduled, centrally acting muscle relaxant, carisoprodol (see ► Chap. 58, “Centrally Acting Muscle Relaxants”).

A marked decline in the availability, prevalence, and therapeutic use of these older sedative-hypnotics is reflected in the marginal incidence of poisonings attributed to their continued use. In 2013, the American Association of Poison Control Centers reported a total of less than 50 exposures and no deaths attributed to glutethimide, ethchlorvynol, meprobamate, and methaqualone out of a sedative-hypnotics/antipsychotics category total of greater than 150,000 exposures and 363 deaths [4]. Because these drugs continue to exhibit persistent availability they are briefly discussed.

Glutethimide

Glutethimide was introduced in the mid-1950s and became widely known in the 1970s for its abuse potential, especially when combined with opioid drugs, such as codeine. Glutethimide is a compound of relatively low water solubility that

exhibits slow, erratic gastrointestinal absorption; is distributed relatively broadly (volume of distribution 2.7 L/kg); and undergoes inducible biotransformation and elimination through cytochrome P-450 pathways to active metabolites (e.g., 4-hydroxyglutethimide and 2-phenylglutarimide) with an elimination half-life that ranges from 5 to 22 h [70].

Structurally similar to phenobarbital, glutethimide has sedative-hypnotic effects that are similar to the effects of barbiturates, but it lacks anticonvulsant properties. It also possesses potent antimuscarinic activity (see ► Chap. 23, “Anticholinergic Syndrome”), including anhidrosis and pupillary mydriasis. Acute toxicity from glutethimide is complicated by slow, erratic absorption and redistribution from tissues, resulting in a cyclic pattern of coma, convulsions, hypotension, and respiratory failure; pulmonary edema and renal failure also have been reported [71–73]. The close structural similarity of glutethimide to phenobarbital also explains the occurrence of false-positive results on urine immunoassays for barbiturates after glutethimide administration.

Aggressive life support is the essence of the intensive care management after glutethimide overdose. Initial enteral administration of activated charcoal in the patient with a protected airway to prevent further absorption may be of benefit, given the potential for delayed gastric emptying associated with a drug that possesses anticholinergic and barbiturate-like depressant properties. However, activated charcoal has not been shown to alter the outcome of these patients. There is no clinical benefit from the use of extracorporeal clearance modalities (e.g., hemodialysis) in the management of glutethimide poisoning [73, 74].

Ethchlorvynol

Ethchlorvynol was initially marketed in the 1950s as a hypnotic agent and formulated in a capsule containing a liquid form of ethchlorvynol and polyethylene glycol diluent. These capsules are noted for the characteristic vinyl (plastic-like)

odor and reported to occur on the breath of the overdose patients. A highly lipophilic and volatile compound, ethchlorvynol has a rapid absorption and onset of action with the latter typically occurring before peak post absorption serum concentrations are reached (1–1.5 h). Because of its absorption kinetics and volume of distribution (~2.8 L/kg), a second, post-redistribution peak concentration is seen about 10 h following ingestion [70, 75]. Hepatic metabolism is extensive, with less than 1% urinary excretion occurring as the parent compound; elimination half-life ranges from 10 to 25 h at therapeutic doses to greater than 100 h after overdose.

The pharmacologic properties of ethchlorvynol are similar to those of barbiturates, including the capability for anticonvulsant and sedative-hypnotic actions. Prolonged (>10 days) coma, respiratory failure, bradycardia, hypotension, hyporeflexia, and hypothermia are characteristic of the clinical presentation after oral overdose. Pulmonary edema occurs more frequently after parenteral overdose and probably results from an increase in pulmonary alveolar membrane permeability as an effect of the drug itself, rather than the coformulate excipient [76, 77]. Bullous skin lesions and rhabdomyolysis are relatively common, although nonspecific, peripheral organ system complications of ethchlorvynol overdose, particularly in cases in which initial clinical discovery is delayed [75]. Given the potential for an extended period of severe intoxication after ethchlorvynol overdose, prolonged supportive care in an intensive care unit is required.

Meprobamate

Meprobamate was introduced in the 1950s and used widely for sedation and anxiolysis until it was recognized to be highly addictive and relatively lethal in overdose. Carisoprodol, its metabolic precursor, continues to be marketed as a muscle relaxant (Soma[®]) and continues to be associated with risks of toxicity, abuse, tolerance, and withdrawal (see ► Chap. 58, “Centrally Acting Muscle Relaxants”) [4, 78–80].

Meprobamate absorption, similar to that of carisoprodol, has been characterized in some cases of overdose as erratic or prolonged, and may reflect formation of gastric concretions [81, 82]. Although there is (very limited) clinical data supporting the use of repeat administration of activated charcoal, this is not routinely indicated [83, 84]. Activated charcoal administration has not been shown to alter the outcome in these patients. Because of the possibility of obtundation of mental status activated charcoal should be given cautiously, if at all, in the non-intubated patient. Coma, clonus, seizures, profound and protracted hypotension, pulmonary edema, and cardiac dysrhythmias all have been reported after massive meprobamate overdose [82]. Cardiovascular depression may occur at doses responsible for coma. Although unproven, theoretical support for the use of hemodialysis to enhance meprobamate elimination includes its known low molecular weight and volume of distribution (0.7 L/kg), and degree of protein binding (20%) [70]. In addition, due to a risk of delayed or recurrent clinical deterioration after acute overdose, intensive monitoring and care should be maintained for 24 h following recovery from significant clinical effects.

Methaqualone

Methaqualone was withdrawn from the regulated U.S. market in 1983 after it was found to be relatively ineffective as a long-term maintenance drug in the treatment of anxiety and sleep disorders and developed widespread notoriety as a substance of abuse. It is pharmacologically similar to glutethimide and ethchlorvynol, with a slow biphasic pattern of elimination and prolonged duration of CNS depression following overdose. As a result of its selective inhibition of polysynaptic spinal reflexes, toxicity is notable for coma plus hyperactive motor dysfunction, clinically manifested as increased muscle tone, hyperreflexia, clonus, and myoclonus [85–87]. Another structurally related compound, methyl-methaqualone, has been reported to result in similar clinical effects [88]. It has been

suggested that case reports of retinal and gastrointestinal hemorrhage may be explained on the basis of drug-induced effects on platelet dysfunction and coagulation factors [89, 90].

Aggressive supportive care of severe methaqualone toxicity should be directed at control of motor hyperreactivity (e.g., intravenous benzodiazepines or neuromuscular blockade or both). If paralytic agents are used, continuous electroencephalogram should be considered.

Diagnosis

As with many drug-induced illnesses, the history of use or abuse of a sedative-hypnotic is often a starting point for patient evaluation and management. Important historical questions include: What medications is the patient taking? How much and for how long was the patient taking the medication? What medications did they have access to?

The laboratory detection and identification of benzodiazepines in blood and urine can be challenging based on the available assays. The relatively low sensitivity and specificity of immunoassay methods (e.g., enzyme multiplied immunoassay technique) and limited ability to detect benzodiazepines in biologic matrices by more specific methods (e.g., gas chromatography/mass spectrometry) are explained by the low concentrations of some drugs in urine and the excretion of conjugated metabolites [5, 7, 8]. Routine urine drug screening may include false positive or false negative results. And although specific drug testing methods are often valuable during forensic investigations, they rarely change initial patient management. In some circumstances, checking other drug concentrations (e.g., ethanol, phenytoin, phenobarbital) may assist in diagnosing (or ruling out) other drug causes for the patient's condition.

The diagnosis of sedative-hypnotic withdrawal is primarily determined by the presence of signs and symptoms of GABA-agonist withdrawal in a patient with a history of long-term use or abuse. An agitated patient who responds minimally to escalating doses of a rapidly acting

benzodiazepine (e.g., diazepam) is also suggestive of sedative-hypnotic withdrawal. This diagnosis is further supported by the presence of a causative agent (or metabolite) on routine or comprehensive toxicologic testing; though limitations of such testing must be appreciated.

Chloral hydrate toxicity may be signaled by the pear-like odor associated with its use, which may alert the clinician to the diagnosis. CH tablets are radiopaque on an abdominal x-ray. Because CH's metabolite, TCE, has a long half-life and is detectable in blood and urine, it can be tested for in suspected exposures [91].

Treatment

The management of acute benzodiazepine toxicity is mainly supportive. Other causes for altered sensorium (e.g., hypoglycemia) should always be investigated. Appropriate initial intervention include cardiopulmonary (with pulse oximetry and perhaps end tidal CO₂) monitoring, and based on the patient's clinical status, supplemental oxygen, intravenous fluids and dextrose. Naloxone administration should be considered in patients with hypoventilation (Level of Evidence (LoE) I). The potential for aspiration should remain a concern as long as the patient is comatose. If clinical presentation occurs within one hour of ingestion, oral (voluntary) administration of a single dose of activated charcoal may be considered (LoE I). However, activated charcoal has not been shown to alter the outcome in these overdoses and should be given cautiously to non-airway protected patients who have taken a drug that might obtund their mental status.

Flumazenil is a competitive antagonist at the benzodiazepine binding site of GABA_A receptors and reverses the CNS depressant effects of benzodiazepines. (LoE I) Flumazenil should also reverse the effects of benzodiazepine-like agents (e.g., zolpidem) as well [6, 92]. The degree and duration of effect of flumazenil on benzodiazepine-induced respiratory depression may be limited, however.

The use of flumazenil is safest in cases of acute, isolated benzodiazepine toxicity (e.g., in young

children after an exploratory ingestion and patients not on chronic benzodiazepine therapy and in whom there is a low suspicion for coingestants). Successful reversal of CNS depression in these instances does not obviate the need for further close monitoring because re-sedation may recur. Continuous infusion of flumazenil (in appropriate patients) has been reported but is not routinely recommended. The indiscriminant use of flumazenil may precipitate seizures, cardiac arrhythmias and/or acute withdrawal [93]. The chapter on flumazenil provides a more detailed discussion regarding the mechanism of action, contraindications, and administration of this antidote..

Because uneventful recovery from acute benzodiazepine toxicity usually occurs within 24 h after supportive care, extracorporeal enhancement of drug elimination is not indicated. Hemodialysis would not be expected to change clinical outcome for several reasons, including benzodiazepines' high degree of protein binding.

Treatment: Chloral Hydrate

All CH overdose patients should be observed closely on a cardiac monitor for at least 3 h after ingestion and for at least 24 h if they develop clinical toxicity. (LoE II-3) Appropriate supportive measures, including endotracheal intubation, mechanical ventilation, and intravenous fluid volume replacement, should be provided as they are clinically indicated. Tachydysrhythmias induced by CH poisoning should be treated with a β -adrenergic receptor antagonist. (LoE III) Numerous case reports document the successful use of propranolol (1 mg intravenous bolus followed by an infusion of 3 mg/h) or other β -blocker, such as metoprolol (5 mg intravenous bolus), in the treatment of CH-induced dysrhythmias [63, 94–97]. β -Blocker use often has been reported to be successful after failure to control the dysrhythmia with other drugs, such as lidocaine, procainamide, sodium bicarbonate, or magnesium. Continuous cardiac monitoring is warranted, and repeated dosing of the β -blocker may be required. Cardioversion or defibrillation

also has been employed to terminate dysrhythmias associated with CH poisoning [96]. The administration of nonselective adrenergic agonists (e.g., dopamine, norepinephrine) to CH-poisoned individuals has been associated with an increase in dysrhythmias [37, 96, 98]. These agents should be used with caution or avoided in favor of α -selective agonists (e.g., phenylephrine) in the treatment of CH-induced hypotension.

Case reports suggest that the use of flumazenil in CH overdose may reverse CH-induced sedation as well as precipitate ventricular dysrhythmias [99, 100]. The induction of acute withdrawal states by naloxone or flumazenil administration may increase the risk of TCE-induced dysrhythmias by increasing the release of endogenous catecholamines [63]. (LoE III) Naloxone and flumazenil should not be used in the management of CNS depression associated with CH overdose.

Several reports show favorable outcomes after the use of hemodialysis in severe CH-induced toxicity, including a pregnant patient with malignant cardiac dysrhythmias [44, 54, 96, 101, 102]. (LoE III) There is no published clinical trial evidence to support outcome benefit, but it seems reasonable to recommend hemodialysis when the CH poisoning is severe, prolonged, or refractory to other therapeutic interventions.

Treatment: Acute Sedative-Hypnotic Withdrawal

Appropriate management of acute sedative-hypnotic withdrawal should focus on the use of GABA-agonists. It should be remembered that patients may have a broad cross-tolerance among different drugs within the sedative-hypnotic class, depending on their mechanism of action. Rational choices of treatment are based on the relative safety and reliability of systemic administration, speed of therapeutic onset, and duration of effect. In general, agents with a rapid onset and long half-life (with or without active metabolites), such as diazepam, are pharmacologically desired. The optimal end point of pharmacotherapeutic titration with an intravenous benzodiazepine (e.g.,

diazepam) is resolution of sympathetic hyperactivity to the point of mild, rather than profound, sedation. The dose required to achieve this is highly variable and should be based on the closely monitored clinical response to incremental enteral or parenteral administration. The frequency of drug administration is based on the patient's clinical status. Patients with significant neurological and cardiovascular signs of sedative-hypnotic withdrawal should be continuously monitored, frequently (e.g., every 15 min) re-assessed and re-dosed as needed. See ► [Chap. 27, “Withdrawal Syndromes”](#) for a more complete and general discussion of drug withdrawal and its management.

The failure of benzodiazepine therapy to reverse sedative-hypnotic withdrawal manifestations may reflect inadequate dosing, inadequate cross-tolerance secondary to differences in GABA_A-receptor subtype affinity or another etiology for the patient's condition.

Long-term treatment of ASH dependence, including detoxification and discontinuation of therapy, can be accomplished safely and reliably using one or a combination of tapering regimens employing the same drug or a long-acting substitute (e.g., phenobarbital) [103–107]. (LoE II-3) Non-GABA-agonist adjunctive therapy is not routinely needed during inpatient treatment. Although this withdrawal state, and treatment, share very similar pathophysiology with alcohol (or any GABA-agonist) withdrawal, there is no consensus on definitive treatment [108]. Optimal management of significant withdrawal requires a facility capable of addressing the medical complications associated with acute or pre-existing co-morbidities (e.g., sepsis, hypertension) and potential complications of treatment (e.g., excessive sedation and loss of airway). Access to psychological and social services resource should also be available for long-term behavioral treatment [109].

Clinically significant benzodiazepine withdrawal may occur within hours of recovery from the acute sedative effects depending on the underlying degree of pharmacodynamic tolerance and the elimination kinetics of the specific drug. Once the patient has returned to baseline status,

maintenance therapy with the same (or other, related) drug is suggested in patients who are chronically taking the medication. Based on available data, all patients should be monitored for evidence for acute withdrawal following a sedative-hypnotic overdose. Although scientific evidence is lacking, anecdotal and our personal experience suggests that withdrawal from some GABA-agonists (e.g., alprazolam and carisoprodol) is best treated with the specific agent.

Special Populations

Pediatric Patients

Children who have received oral or parenteral benzodiazepines for conscious sedation may experience paradoxical reactions consisting of restlessness, disorientation, agitation, and combativeness [8, 110]. These adverse reactions have been observed to occur at relatively low (~1%) frequencies and are even less common in adults. Case experience has shown that flumazenil may be effective in reversing excessive sedation or paradoxical reactions that occurs after iatrogenic benzodiazepine administration [111, 112].

Pregnant and Breast-Feeding Patients

Most benzodiazepines, including alprazolam, and lorazepam, have been classified by the FDA as teratogenicity category D drugs (meaning there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.) but the benefits from use in pregnant women is often acceptable based on the indication and patient's condition or when safer drugs cannot be used or are ineffective. Exceptions to this generalization are triazolam, temazepam, quazepam, estazolam, and flurazepam, which are classified as category X (contraindicated in pregnancy) drugs; zolpidem, zaleplon and eszopiclone are classified as category C (Animal reproduction studies have shown an adverse effect

on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks) [113, 114].

Two neonatal syndromes that have been described after relatively high-dose (>30 mg) or prolonged maternal diazepam administration during labor are floppy infant syndrome (lethargy, hypotonia, sucking difficulties) and withdrawal (tremors, irritability, hypertonicity, vomiting, diarrhea, vigorous sucking) [113, 115]. On the basis of their known excretion into human breast milk and reports of clinical withdrawal and excessive sedation in breast-feeding infants, it is recommended that benzodiazepines be used with caution in breast-feeding women [113, 116].

Elderly Patients

Elderly individuals are at greater risk for more severe or prolonged toxicity as a result of age-dependent differences in pharmacokinetic and pharmacodynamic responses to the administration of benzodiazepines. Drug-drug interactions are also possible in this age group. Flumazenil administration, if done at all, should be done with even more caution.

Special Populations: Chloral Hydrate

The use of CH has been associated with higher rates of adverse effects, including inadequate sedation, excessive sedation in patients with obstructive sleep apnea, wheezing, mental retardation, and diseases of cerebral white matter or the brainstem [117, 118]. A study of 52 pregnant women who received CH while in active labor did not report any adverse maternal or fetal effects [119]. Analysis of fetal (cord) blood revealed significant concentrations of CH, TCE, and TCAA. Low, but measurable concentrations of CH is found in breast milk that may be too low to produce neonatal effects [119–121]. Data suggest that neonates and preterm infants have impaired abilities to metabolize and excrete CH and its metabolites [122]. Reports have documented

significant increases in the half-life of TCE to 40 h in neonates and critically ill children [123, 124]. Published reports indicate the potential for increases in serum bilirubin (direct and indirect) in infants receiving CH [125, 126]. This apparent dose-related phenomenon may reflect competition between CH and CH metabolites and bilirubin for conjugation in the immature liver.

Indications for ICU Admission in Benzodiazepine Toxicity

Established or impending respiratory failure.

Prolonged or profound level of obtundation.

Withdrawal syndrome, refractory to initial treatment.

Reversed coma using flumazenil (necessity of adequate monitoring)

Key Points in Benzodiazepine Toxicity

1. Depressed sensorium without serious respiratory, cardiovascular, or other neurologic manifestations represents the typical clinical presentation of acute or chronic benzodiazepine or benzodiazepine-like drug (e.g., zolpidem) toxicity.
2. Paradoxical neuropsychiatric reactions (e.g., restlessness, agitation) occur uncommonly but with apparently greater frequency in children and elderly individuals.
3. The mainstay of treatment for benzodiazepine toxicity is supportive care.
4. Flumazenil, a benzodiazepine receptor antagonist, should be used selectively and with caution in the management of acute or chronic benzodiazepine and benzodiazepine-like drug toxicity, particularly when pharmacodynamic tolerance to the effects of benzodiazepine receptor agonists or concomitant proconvulsant (e.g., tricyclic antidepressant) intoxication is considered likely.

5. Reinstitution of maintenance regimen doses of benzodiazepine or benzodiazepine-like drugs, particularly drugs with relatively rapid elimination kinetics, should be implemented during the early convalescent phase of acute or chronic poisoning to prevent withdrawal.

Key Points in the Management of Chloral Hydrate Toxicity

1. Monitor closely for signs or symptoms of toxicity for at least 3 h after ingestion.
2. Provide supportive care, including intubation, oxygenation, and ventilation, when clinically indicated.
3. Use a β -adrenergic blocker (e.g., propranolol) for tachydysrhythmias.

Indications for ICU Admission in Chloral Hydrate Toxicity

Neurologic instability (coma, seizures)

Respiratory failure

Cardiac dysrhythmias

Pharmacokinetics of Chloral Hydrate

Volume of distribution: 0.6 L/kg (CH)

Protein binding: TCE, 40%; TCA, 85%

Mechanisms of elimination: CH, <10% excreted unchanged in urine; TCE, renal excretion as urochloralic acid or oxidation to TCAA; TCAA, renal excretion

Plasma half-life: CH, approximately 4 min; TCE, 10 h (can be longer in overdose); TCAA, 67 h (can be longer in overdose)

Metabolites: chloral hydrate (CH) undergoes rapid conversion to two metabolites: trichloroethanol (TCE) (active) and trichloroacetic acid (TCAA) (inactive).

Barbiturates were originally introduced as sedative-hypnotics and anticonvulsants in the early 1900s. Secondary to the frequency of their prescription and illicit use, unintentional/intentional overdoses and the ensuing toxicities became commonplace. Barbiturates are hazardous and have the highest risk of morbidity and mortality among all sedative-hypnotics [1]. The use of newer, relatively less-toxic medications (such as benzodiazepines) has largely supplanted the routine use of barbiturates. As a result, the incidence of serious toxicity related to barbiturate use has declined. Nevertheless, barbiturates are occasionally used today. Examples include phenobarbital and butalbital, which currently are prescribed for seizure disorders and migraine headaches, respectively [2]. Phenobarbital is also often employed to treat moderate-to-severe γ -aminobutyric acid (GABA)-agonist withdrawal [3]. Primidone, used as an anticonvulsant and in management of GABA-agonist withdrawal, is metabolized to phenobarbital [4]. Barbiturates such as methohexital are used for induction of anesthesia, and pentobarbital is commonly relied on for control of intracranial pressure and status epilepticus in intensive care units [5, 6]. Barbiturates are sometimes used as adjunctive therapy for neonatal hyperbilirubinemia [7]. Illicit drug use also may involve barbiturates because of their high abuse potential. These agents have also been employed in self-harm gestures, particularly in those populations with access to these medications, such as healthcare and veterinary workers.

Fig. 1 Chemical structures of barbituric acid (a), phenobarbital (b), butabarbital (c), pentobarbital (d), butalbital (e), and thiopental (f)

Consequently, clinicians must be aware of the potential toxicities due to accidental or intentional ingestions of barbiturates and remain astute as to the potential addictive properties of barbiturates, with the attendant risk for tolerance and abstinence-induced withdrawal. Finally, secondary to their potent clinical effects, these agents have been employed in criminal poisonings and suicide attempts [8, 9].

Biochemical and Pharmacokinetic Properties

All barbiturates are barbituric acid (2,4,6-trioxohexahydropyrimidine) derivatives (Fig. 1) [10]. Barbiturates have traditionally been classified as short-acting, intermediate-acting, and long-acting based upon their duration of action and hepatic metabolism. These characteristics are influenced primarily by the lipid solubility and consequent distribution into tissues, rather than the actual pharmacologic elimination half-life. Lipid solubility, potency, and onset and duration of action are functions of various substitutions made at different positions on the common barbituric acid structure (see Fig. 1). Agents with long side chains, such as thiopental, tend to display a high degree of lipid solubility and potency, with a rapid onset and short duration of action. In contrast, phenobarbital has a shorter side chain,

which confers a relatively lower lipid solubility, lower potency, slower onset, and longer duration of action. Substitution of a phenyl group at the C5 position results in anticonvulsant activity, as observed with phenobarbital and mephobarbital. In general, the more lipid-soluble the barbiturate compound, the more protein-bound it is in the plasma [11]; for example, thiopental is highly protein-bound, while phenobarbital is less so. Protein binding plays an important role in the ability to remove a barbiturate effectively from the plasma using hemodialysis [12].

Most barbiturates are well absorbed after oral administration and distribute widely to most body tissues, including the placenta and breastmilk, and undergoing nearly complete hepatic metabolism through cytochrome P₄₅₀ systems to inactive compounds, which are subsequently renally excreted [9]. Two barbiturates, mephobarbital and metharbital, are endogenously converted to phenobarbital and barbital [1]. Renal excretion is more important for long-acting barbiturates, with nearly 25% of phenobarbital being excreted unchanged in the urine. Elimination of barbiturates is slower in neonates, elderly patients, and those with hepatic and renal dysfunction; pregnancy may increase the half-life of a barbiturate, owing in part to an expanded volume of distribution Table 1.

Several noteworthy drug interactions occur with barbiturate administration. The sedative-hypnotic effects of barbiturates may be enhanced with

Table 1 Pharmacokinetics of Barbiturates

Barbiturate	Duration of action (hr)	pKa	Protein binding (%)	Elimination route	V _d (L/kg)
Ultra-short-acting					
Thiopental (Pentothal)	0.3	7.60	80	Hepatic	1.3–6.9
Methohexital (Brevital)	0.3	7.90	73	Hepatic	1.1–2.6
Short-acting					
Pentobarbital (Nembutal)	3	7.96	40–70	Hepatic	0.65–1.2
Secobarbital (Seconal)	3	7.90	52–57	Hepatic	1.5
Butalbutal (Fiorinal)	3–4	7.6	NA	Hepatic	NA
Intermediate-acting					
Amobarbital (Amytal)	3–6	7.75	60	Hepatic	1.0–1.27
Aprobarbital (Alurate)	3–6	NA	NA	Hepatic	NA
Butabarbital (Butisol)	3–6	7.74	NA	Hepatic	0.78
Long-Acting					
Phenobarbital (Luminal)	6–12	7.24	51	Renal (25–30%)	0.5–0.7
Mephobarbital (Mebaral)	6–12	7.8	40–60	Renal (35–40%)	2.8
Primidone (Mysoline)	6–12	13.0	19	Renal (15%)	1.0

NA, not available; V_d, volume of distribution

concomitant administration of other sedative agents such as ethanol or benzodiazepines. Repeated administration of barbiturates may induce hepatic CYP₄₅₀ 3A4, enhancing the metabolism of oral contraceptives, warfarin, vitamin D, tricyclic antidepressants, sulfonamides, doxycycline, corticosteroids, phenytoin, and barbiturates themselves [4].

Pathophysiology of Therapeutic and Toxic Effects

Barbiturates generate their sedative-hypnotic effects in the central nervous system via several mechanisms. They promote GABA binding to the GABA_A chloride channel complex, increasing the duration of chloride channel opening. At high concentrations, they may directly open the GABA_A chloride channel [13, 14]. The result of these actions is increased chloride content in the nerve cell, hyperpolarizing the membrane and depressing neuronal electrical activity [15]. Barbiturates also can reduce excitatory α -amino-3-hydroxy-5-methyl-4-isoxazole propionate glutamate-induced depolarization [13].

Barbiturates may inhibit nicotinic neurotransmission in autonomic ganglia. Other effects of barbiturates include depression of the medullary respiratory center, inhibition of myocardial contractility and conduction as a result of their “membrane-stabilizing” actions (i.e., fast sodium channel blockade), and suppression of gastrointestinal motility [13].

Long-term barbiturate use may produce tolerance to its sedative-hypnotic effects. This phenomenon is related partially to barbiturate induction of hepatic microsomal enzymes (pharmacokinetic tolerance). Additionally, GABA_A receptor downregulation occurs with chronic use, which progressively increases as the drug dose increases (pharmacodynamic tolerance) [16].

Clinical Presentation and Life-Threatening Complications

The clinical presentation of the acutely barbiturate-poisoned patient may vary depending on the patient’s age and duration of use of the drug. A given dose of barbiturate may cause severe toxicity in a first-time user but only minor

impairment in the long-term user because of the latter's pharmacodynamic tolerance to the drug. Barbiturate overdose management decisions should be based primarily on the clinical status of the patient and, to a lesser degree, to the serum barbiturate concentration, if available.

In general, acute intoxication with barbiturates may be clinically indistinguishable from that caused by other central nervous system depressant and sedative-hypnotic compounds, such as ethanol or benzodiazepines. These clinical manifestations center around central nervous system depression; somnolence, ataxia, slurred speech, and incoordination are often considered cardinal signs of barbiturate toxicity. Vital sign stability and deep tendon reflexes may be preserved in mild barbiturate poisoning. Moderate or severe poisoning frequently progresses to lethargy, bradypnea, hypopnea, and diminished deep tendon reflexes [17].

Patients with severe barbiturate intoxication classically present with coma, hypothermia, and circulatory collapse. Neurologic findings may include nonreactive pupils, loss of other brainstem reflexes (corneal, oculovestibular), absent deep tendon reflexes, and presence of pathologic reflexes (i.e., Babinski sign) [17]. These manifestations mimic and can easily be mistaken for clinical brain death, which may be further suggested by isoelectric electroencephalogram tracings. Skin bullae may be present but are nonspecific findings and are occasionally observed as a complication of other central nervous system depressant poisonings. Deleterious effects from other ingested toxins, anoxia, trauma, aspiration pneumonia, and rhabdomyolysis all may compound the initial insult and may cloud the clinical picture.

Patients who chronically use or abuse barbiturates may experience withdrawal symptoms during the recovery phase of an acute poisoning episode or during other periods of medication abstinence. The severity of the withdrawal syndrome is a function of the daily dose of barbiturate and the degree of dependence [16]. This clinical syndrome, similar to withdrawal from other

GABA agonist agents, typically manifests within 24 h and peaks depending on the elimination half-life and duration of effect of the barbiturate used. Early signs and symptoms may include restlessness, anxiety, confusion, tremor, nausea, abdominal cramps, tachycardia, and diaphoresis. Progression to more severe signs and symptoms may occur and can include increased muscular tone, delirium, and seizures. In addition, progressive autonomic dysfunction and cardiovascular collapse may occur in severe cases. Short-acting barbiturates such as secobarbital tend to be associated with onset of withdrawal symptoms within the first 48–72 h of their discontinuation, while withdrawal from long-acting barbiturates, such as phenobarbital, typically peaks in approximately 1 week. The abstinence syndrome usually clears within 14 days [1]. This syndrome may be seen in the intensive care unit in patients receiving continuous barbiturate administration for sedation [18].

Chronic adverse effects of barbiturates include induction of several enzyme systems, including hepatic microsomal CYP₄₅₀ 3A4, the mitochondrial enzyme aminolevulinic acid synthetase, and the cytosolic enzyme aldehyde dehydrogenase [13]. Induction of aminolevulinic acid synthetase may precipitate exacerbations of underlying porphyria because of enhanced porphyrin synthesis [13].

Anticonvulsant hypersensitivity syndrome is a well-recognized pharmacogenetic and idiosyncratic reaction to anticonvulsant therapy with aromatic-ring-containing agents such as phenobarbital, phenytoin, primidone, and carbamazepine. The pathogenesis of this syndrome is thought to stem from formation of reactive metabolic intermediates (arene oxides) through the actions of hepatic microsomal enzymes. If these arene oxides are not sufficiently detoxified by epoxide hydrolase, they may covalently bind to cell membrane constituents to form neoantigens that trigger hypersensitivity reactions. The clinical manifestations of anticonvulsant hypersensitivity syndrome arise most frequently on first exposure

to the drug and occur usually within several days to weeks of initiation (earlier in previously-sensitized patients). Fever, malaise, pharyngitis, cervical lymphadenopathy, atypical lymphocytosis, eosinophilia, and cutaneous eruption are typically part of the initial clinical presentation of the hypersensitivity syndrome. The rash may range from an exanthemous eruption to Stevens-Johnson syndrome or toxic epidermal necrolysis. Additional visceral organ involvement may include hepatitis, myocarditis, pericarditis, nephritis, pneumonitis, and thyroiditis [19].

Diagnosis

Laboratory tests obtained for a patient with suspected barbiturate intoxication should include a finger-stick blood glucose, electrolyte panel, serum creatine phosphokinase, and an electrocardiogram. If there is concern for the possibility of acute overdose, it is advisable also to screen for acetaminophen and salicylate poisoning. Urine immunoassay tests, such as enzyme-magnified immunoassay techniques, readily detect many barbiturates at plasma concentrations associated with toxicity. Drugs such as glutethimide, a nonbarbiturate sedative-hypnotic, may cause false-positive results [4]. In addition, barbiturates other than phenobarbital cross-react with the latter compound in some immunoassays [20]. Gross crystalluria has been reported with primidone toxicity; this drug is an anticonvulsant that undergoes biotransformation to phenobarbital and involves renal tubular precipitation of the parent compound [4].

Serum barbiturate concentrations do not always correlate with toxicity, particularly in the barbiturate-dependent patient. Prognostic or forensic information may be provided by serum drug concentrations; however, in barbiturate-poisoned patients, values greater than 35 mg/L of short-acting barbiturates such as secobarbital and greater than 80 mg/L (approx 350 $\mu\text{mol/L}$) of long-acting barbiturates

such as phenobarbital are potentially lethal [1]. In addition, serial serum barbiturate concentrations may assist in determining the need for continuing medical treatment or in the declaration of brain death after initial biologic detection of barbiturates.

Treatment

Standard treatment of acute barbiturate poisoning begins with aggressive airway management and ventilatory support as clinically indicated. Careful attention to hemodynamic monitoring is crucial. If hypotension occurs and persists despite aggressive fluid volume resuscitation, the addition of intravenous vasopressors such as norepinephrine may be required to achieve hemodynamic stability. Forced diuresis is not recommended because of the attendant risks of sodium and fluid overload and probable lack of efficacy. Severe hypothermia should be treated by vigorous rewarming measures.

If a patient presents early after acute oral overdose, administration of a single dose of activated charcoal may be considered. However, it should be administered with caution in a nonintubated patient as the barbiturate may cause a lessening of their level of consciousness during activated charcoal administration, thus enhancing the risk of aspiration. Multiple doses of activated charcoal may reduce the duration of coma in an acutely phenobarbital intoxicated patient (Level of Evidence: II-1) [21–23]. Caution is advised with this intervention because bowel motility may be compromised in a barbiturate-toxic patient. Multi-dose activated charcoal (MDAC) administration must be performed prudently to minimize the risk of aspiration, which generally requires airway-protective measures and oronasogastric tube placement in comatose patients. There is no evidence to support the use of MDAC and urinary alkalization with short- or medium-acting barbiturates.

Indications for ICU Admission in Barbiturate Poisoning

Hemodynamic instability
 Requirement for mechanical ventilation
 Coma
 Severe hypothermia
 Presence of comorbid medical conditions that may complicate therapy (e.g., severe coronary artery disease, congestive heart failure, renal failure)
 Requirement for hemodialysis
 Severe electrolyte disturbances or acidemia
 Actively suicidal patient requiring close observation beyond general hospital floor capability
 Increasing barbiturate level despite aggressive therapy
 Significant withdrawal syndrome

Alkalinization of the urine has been shown to enhance clearance of phenobarbital (Level of evidence: I), which has a pK_a of 7.2. The clearance of barbiturates with higher pK_a values has not been shown to increase in this manner [16]. Administration of sodium bicarbonate intravenously at dosages of 50–100 mmol of sodium bicarbonate in 1 L of 5% dextrose in water infused at 150–250 mL/h, maintaining the serum pH at a level of approximately 7.5–7.55, may effectively promote formation of phenobarbital's ionized form. [1] The rationale behind alkalinization is that because ionized molecules are poorly reabsorbed in the kidney, phenobarbital is ion-trapped under alkaline conditions in the renal tubule and is unable to be efficiently reabsorbed, thereby enhancing elimination. The goal of urinary alkalinization is the maintenance of a urine pH of 7–8 (Level of Evidence: III) [12]. Urinary alkalization may be beneficial in treatment or prevention of accompanying rhabdomyolysis (Level of Evidence: III) [4]. Urinary alkalization to a pH of 8 or above should be done with caution because it may promote hypoventilation.

Hemodialysis and hemoperfusion also can be employed to enhance elimination of long-acting

barbiturates. These drugs are less protein-bound and less lipid-soluble than short-acting barbiturates and can be cleared effectively from the plasma by extracorporeal removal techniques. Indications include severely poisoned patients who are not responding adequately to the aforementioned supportive measures and patients who cannot excrete the barbiturate effectively because of oliguric/anuric renal failure. In addition, the Extracorporeal Treatments in Poisoning work-group provides guidelines for use of extracorporeal removal of barbiturates. These consensus guidelines state that the use of extracorporeal removal techniques should be restricted to cases of severe long-acting barbiturate poisoning. The indications for extracorporeal removal in this setting are the presence of prolonged coma, respiratory depression necessitating mechanical ventilation, shock, persistent toxicity, or increasing or persistently elevated serum barbiturate concentrations despite treatment with multiple-dose activated charcoal. Intermittent hemodialysis is the preferred mode of extracorporeal removal therapy, and multiple-dose activated charcoal treatment should be continued during extracorporeal removal. Cessation of such therapy is indicated when clinical improvement is apparent [37]. Several case reports have shown apparent clinical effectiveness of extracorporeal removal of phenobarbital in patients not responding to other supportive measures [24–27]. Exchange transfusion has been reported as an effective intervention for phenobarbital intoxication in neonates being treated for hyperbilirubinemia [7].

Criteria for ICU Discharge in Barbiturate Poisoning

Mechanical ventilation no longer required as coma resolves or mental status improves
 Vasopressors discontinued
 Hemodynamic stability
 Resolution of coma
 Normothermia
 Resolution of metabolic disturbances
 Decreasing serum barbiturate concentrations

Key Points in the Treatment of Barbiturate Poisoning

1. Aggressive airway management and ventilatory support are key.
2. Administer intravenous fluid (1–2 L) if hypotension is present; if no response, initiate vasopressors (norepinephrine preferred) to maintain systolic blood pressure >90 mmHg and adequate urine output.
3. Perform vigorous rewarming measures for severe hypothermia.
4. Consider administration of one or multiple enteral dose(s) of activated charcoal.
5. Consider urinary alkalization (target urine pH 8) for moderate-to-severe phenobarbital overdose.
6. Consider serial barbiturate levels.
7. If the patient is clinically unstable or has rising serum barbiturate levels despite above measures, hemodialysis or hemoperfusion should be considered.
8. The presence of rhabdomyolysis should be determined.
9. Skin bullae require local wound care; consider tetanus immunization.
10. Consider gastric stress ulcer and deep venous thrombosis prophylaxis in critically ill patients.

Barbiturate Withdrawal

The prevention and management of the barbiturate withdrawal syndrome primarily include gradual tapering of the previously administered medication regimen and institution of the same or a cross-tolerated sedative-hypnotic. In the critical care setting, discontinuation of a short-acting barbiturate such as pentobarbital may be accomplished safely and effectively after initiation of a long-acting barbiturate such as phenobarbital [18]. Withdrawal also may be managed by the administration of a benzodiazepine, such as

diazepam or lorazepam, to control the sympathetic hyperactivity to the point of mild sedation, with care taken not to cause respiratory compromise. Gentle, incremental dose titration may be required at the patient's bedside. When control of withdrawal signs and symptoms is attained, further treatment may entail reintroduction of the barbiturate, depending on the clinical situation [4].

Special Populations**Pediatric Patients**

Neonatal exposure to barbiturates can occur in a variety of clinical scenarios, including administration during delivery or in the intensive care unit and maternal use during pregnancy. Pharmacologic effects of barbiturates in neonates are similar to those in adults, but strict adherence to drug doses and dosing intervals must be maintained because of relatively low levels of phase I enzyme activity in neonates [28]. In addition, phenobarbital has been associated with neonatal hemorrhage owing to a decrease in vitamin K-dependent clotting factors II, VII, IX, and X [28].

Because barbiturates cross the placenta freely, neonatal withdrawal may be encountered. Signs of withdrawal in neonates usually begin 4–7 days after birth and may include overactivity, restlessness, insomnia, hyperphagia, tremor, and vasomotor instability. These signs may persist for weeks to months [16].

Fetal abnormalities also have been reported with use of barbiturates during pregnancy, in a manner similar to that associated with use of phenytoin, trimethadione, and valproic acid. The name *fetal hydantoin syndrome* may be a misnomer because the etiologies of this syndrome also seem to include barbiturates. Clinical manifestations of this syndrome may include facial dysmorphism, prenatal and postnatal growth deficiency, and developmental delay. More recently, the notion of drug-specific syndromes has been

supplanted by the term *fetal antiepileptic drug syndrome* [29, 30].

Pregnant and Breastfeeding Patients

Pregnancy is a multifaceted clinical arena because barbiturate use during this time may affect the mother and the fetus. Barbiturate toxicity in pregnant women may be associated with deleterious effects in the developing fetus, secondary to impaired maternal physiology (e.g., hypotension or hypoxemia). Resuscitation of the mother is the primary goal of the critical care provider.

Barbiturates may be employed in the treatment of pregnant women with epilepsy. Approximately one-third of women with seizure disorders experience escalating seizure frequency when gravid; generalized motor seizures during pregnancy generate fetal bradycardia, decelerations, decreased variability, and intracranial hemorrhage [30]. As a result, optimal seizure control in a pregnant patient is essential to maintenance of fetal health. Although phenobarbital is considered a US Food and Drug Administration pregnancy category D drug (evidence of human fetal risk, but benefit may be acceptable despite potential risk), the risk to the mother and fetus may be greater if seizure control is lost. The lowest amount of drug required to control seizures should be used, and frequent monitoring of drug levels should be maintained [31, 32].

Phenobarbital is excreted in breastmilk, and reports of both infant intoxication and withdrawal have been described. Breastfeeding women prescribed phenobarbital should be instructed to monitor their infant(s) for sedation, and infant phenobarbital levels should be monitored if toxicity is suspected [31].

Elderly Patients

Adverse drug reactions are commonplace in the elderly, who take an average of four or five prescribed medications and two over-the-counter medications [33]. In addition, alterations in the GABA-benzodiazepine receptor complex

associated with aging may make older patients more sensitive to barbiturates [34]. Elderly patients also may have significant comorbid medical conditions that not only can lead to serious problems with medication compliance (e.g., excessive administration of sedative-hypnotics) but also may confound clinical presentation. Not only may the toxicity of the barbiturates be compounded in an elderly patient already taking other sedative-hypnotics or antihistamine medication, but also the diagnosis may be delayed or missed in patients with other medical illnesses clouding the clinical picture.

No specific data are available regarding the absorption, volume of distribution, protein binding, half-life, or changes in metabolism of phenobarbital in the geriatric patient. It has been shown, however, that phenobarbital clearance was reduced in patients aged greater than 40 years when compared with younger patients, and a reduction in maintenance dose was required in the older patients to maintain the same plasma phenobarbital concentration [35]. Decline in renal clearance associated with aging might lead to increased plasma phenobarbital concentrations at the same dose [35].

Veterinary Medicine Professionals

Veterinarians and animal handlers may present a specialized circumstance with respect to sedative-hypnotics. Barbiturates such as pentobarbital are among the common pharmaceuticals used for euthanasia of animals. Additionally, many brand-name agents have been and continue to be employed for this purpose, such as Beuthanasia-D Special[®] (Brand names given here are sold in the USA and are given as examples. These may vary in other countries) (pentobarbital, phenytoin, propylene glycol, and alcohol), Repose[®] (secobarbital, mephensin, and propylene glycol), and Socumb[®] (pentobarbital, isopropanol, and propylene glycol). One of the most popular veterinary euthanasia drugs historically employed was termed T-61[®], a combination agent containing embutramide, mebezonium, and tetracaine solubilized in *N,N*-dimethylformamide. This agent is

still available for veterinary use in many countries. Several case reports of humans using these agents for self-harm exist in the literature [8, 36]. As in other cases of sedative-hypnotic toxicity, aggressive supportive care is the mainstay of therapy in overdose situations involving these agents. In cases of T-61[®] overdose, seizures have been reported to be benzodiazepine-responsive. Pyridostigmine may be effective in cases of skeletal muscle paralysis from this agent, and intubation/ventilatory support addresses the profound respiratory depression from the embutramide component of this agent [8].

Key Points in Barbiturate Poisoning

1. Assessment and treatment should be based primarily on the patient's clinical status, not just serum drug concentrations.
2. Barbiturates can cause isoelectric electroencephalogram (EEG) patterns; the diagnosis of brain death should not be made based on the EEG when these patterns are present.
3. Patients who are taking barbiturates on a long-term basis may develop a severe withdrawal syndrome if they are stopped abruptly.
4. There is no role for forced diuresis.

Bupropion is an atypical antidepressant primarily used for the treatment of depression and as an adjunct for smoking cessation. The United States Food and Drug Administration approved bupropion for the treatment of depression in 1985, but the drug was withdrawn prior to marketing after seizures were reported in four of 55 nondepressed bulimic patients who received it [1]. It was later reported that the risk of seizures with bupropion was comparable to that of other antidepressants, provided the daily dose did not exceed 450 mg, and the drug was reintroduced in 1989 [2, 3]. Today, bupropion is available as immediate-release, sustained-release, and extended-release formulations [4]. It is generally well tolerated at therapeutic doses, with common side effects including insomnia, agitation, dry mouth, and nausea [5]. Given its unique pharmacologic properties, adverse effects frequently encountered with other antidepressants (such as sexual dysfunction, weight gain, and sedation) are rarely seen with bupropion [5]. In overdose, however, bupropion can exhibit significant toxicity, and bupropion abuse is increasingly recognized as an evolving concern. This chapter focuses on the pharmacological and toxicological properties of bupropion, with particular attention to its pharmacokinetics, the clinical manifestations of overdose, and recommendations for management.

Biochemistry and Clinical Pharmacology

Bupropion hydrochloride and its metabolites inhibit the reuptake of norepinephrine and dopamine and antagonize neuronal nicotinic acetylcholine receptors [6]. Bupropion's action as a norepinephrine and dopamine reuptake inhibitor is thought to explain its mechanism in the treatment of depression, which is further substantiated by animal models demonstrating a reduction in antidepressant effects of bupropion in the face of administration of dopamine or norepinephrine antagonists [5]. Inhibition of dopamine reuptake confers anticraving and antiwithdrawal effects, which underlie its role in smoking cessation [5, 6]. Bupropion also exhibits similarities to amphetamine (Fig. 1). Structurally, bupropion contains a phenylethylamine skeleton. In animal models, it produces stimulant effects related to conditioned behaviors similar to other psychostimulants: increases locomotor activity, decreases core body temperature, and reduces food consumption

[6]. These similarities underlie the misuse of bupropion for recreational purposes.

In addition to its effects on neuronal tissue, in overdose bupropion can interfere with cardiac conduction. In a guinea pig heart model, bupropion exhibits weak blockade of the delayed inward rectifier potassium channel (I_{Kr}) at supratherapeutic concentrations ($IC_{50} \sim 34 \mu\text{M}$ (9.38 mg/L) – therapeutic range 0.18–0.36 μM or 0.05–0.1 mg/L [7]. This finding is consistent with the observation that prolongation of the QT interval is seen more often in the setting of overdose than with therapeutic use [7, 8]. Bupropion has also been shown to cause widening the QRS interval at very high concentrations (10 μM ; 2.78 mg/L). This effect is not explained by sodium channel blockade, but rather by inhibition of intercellular gap junction communication in the cardiac conduction system [7].

The pharmacokinetic properties of bupropion are summarized in Table 1. Following ingestion, bupropion absorption is not appreciably influenced by food. It distributes extensively

Fig. 1 Molecular structures of amphetamine and bupropion

Table 1 Pharmacological properties of bupropion hydrochloride

	Molecular weight	Volume of distribution	Protein binding	Water soluble	Time to peak	Elimination half-life
	276 daltons	19 L/kg	82–88%	No	Immediate release: 1.5 h	Parent bupropion: 21 h
Bupropion hydrochloride				(log P 3.47)	Sustained release: 3 h	Metabolites:
					Extended release: 5 h	Hydroxybupropion: 20 h
						Threohydrobupropion: 33 h
						Erythrohydrobupropion: 37 h

throughout the body, with a volume of distribution of 19 L/kg and protein binding ranging from 82% to 88% [9]. The time to peak concentration is dependent on the formulation. The immediate-release tablet achieved peak concentrations at 1.5 h [9], but modified-release formulations prolong absorption by design. The sustained-release formulation incorporates bupropion into a methylcellulose matrix, while the extended-release formulation consists of a core of bupropion surrounded by controlled release and moisture barrier coatings. Following therapeutic doses, these delivery systems result in peak concentrations at 3 h and 5 h, respectively [9]. Limited evidence suggests that these kinetics can be altered following overdose. One report of a large overdose (5.7 g) of sustained-release bupropion observed a time to peak concentration of more than 8 h post-ingestion, with no history of any co-ingestants [10]. Another report involving an unknown amount of extended-release bupropion observed peak levels 13 h after presentation [11]. In this case, however, the comprehensive toxicology screen was also positive for chlorpheniramine [11] which may have delayed absorption. Pharmacobezoar formation has also been postulated as a mechanism for delayed absorption [12].

The three major metabolites of bupropion are hydroxybupropion, threohydrobupropion, and erythrohydrobupropion [6]. The formation of hydroxybupropion is mediated primarily by CYP2B6, with other CYP isoforms playing minor roles [6, 9]. Threohydro- and erythrohydrobupropion formation result from the activity of carbonyl reductase, a family of nonmicrosomal enzymes found in liver and intestinal tissue [6, 9]. All three major metabolites are pharmacologically active. Hydroxybupropion demonstrates 50% of the antidepressant activity of the parent bupropion, while threohydro- and erythrohydrobupropion are approximately 20% as effective as an antidepressant [6, 9]. The hydroxybupropion and threohydrobupropion metabolites accumulate to a greater extent than the parent compound at steady state, and in a mouse model, all three metabolites were shown to be more proconvulsant than the parent compound [13]. The $t_{1/2}$ of bupropion, hydroxybupropion,

threohydrobupropion, and erythrohydrobupropion are 21 h, 20 h, 33 h, and 37 h, respectively [9]. Bupropion is extensively metabolized by the liver, with less than 0.5% of the parent compound excreted unchanged in urine and less than 10% in feces [6, 9]. In addition to being a substrate for CYP2B6, bupropion has been shown to be a strong inhibitor of CYP2D6 [6].

The clinical significance of hepatic and renal impairment on the disposition of bupropion and its metabolites is uncertain. In an open-label study, the elimination half-life of the hydroxybupropion metabolite was 32.2 h in patients with alcoholic liver disease, as compared to 21.1 h in healthy volunteers; however, there were minimal differences in half-lives of the parent compound and the threohydro- and erythrohydrobupropion metabolites [14]. A separate study found no differences in pharmacokinetic parameters in nine patients with mild to moderate cirrhosis compared to healthy volunteers [9]. In a study involving eight hemodialysis patients, concentrations of bupropion and its metabolites were measured serially over 7 days following a 150 mg dose. Bupropion concentrations were similar regardless of renal function; however, the concentration of metabolites was two to threefold higher in patients with renal impairment [15]. Predictably, this study also demonstrated that dialysis has little influence on bupropion clearance, in keeping with the drug's lipophilicity and large volume of distribution [9].

Clinical Presentation

Therapeutic Dose

At therapeutic doses, bupropion is relatively well tolerated. Common adverse effects include nausea, xerostomia, agitation, and insomnia [9]. Compared to other antidepressants, bupropion has little effect on serotonergic transmission. Consequently, many of the undesirable effects of conventional antidepressants such as weight gain, sexual dysfunction, and sedation are uncommon during treatment with bupropion. Indeed, in some instances, bupropion has been used to counter

Table 2 Summary of case series examining bupropion overdose

Study	Design	Formulation	Number of cases	Median age	Cases with seizure	Mean dose for seizure	Mean time of seizure onset	Seizure onset time range	Deaths
Spiller et al. (1996) [16]	3-year retrospective case series	Immediate release, IR	58	30 y	21%	3,078 g	3.7 h	1–8 h	0
Shepherd et al. (2004) [17]	2-year retrospective case series analysis	Sustained release, SR (75% of cases)	385	29 y	11%	n/a (Range 600 mg to 18 g)	4.3 h	1–14 h	2
Starr et al. (2009) [18]	1-year retrospective and 2-year prospective case series	Extended release, XL	117	25.8 y	31.6%	4.35 g ^a	7.3 h	0.5–24 h	1

y years of age, g grams, h hours

^aThis dose applies to patients over the age of 12 years

these effects [5]. Even at therapeutic doses, bupropion demonstrates a dose-dependent risk for seizures with a rate of 0.1% at doses up to 300 mg/d and 0.4% at doses up to 450 mg/d [2, 9].

Overdose

Bupropion overdose is often accompanied by serious neurologic and cardiovascular toxicity. Most of our understanding of the natural history of bupropion overdose derives from case reports and case series.

Neurologic Toxicity

Several case series demonstrate that seizures are a hallmark of bupropion overdose. A large retrospective review of nearly 7,400 single-agent bupropion exposures found that seizures occurred in 15% of patients [4]. A major limitation of this study was the lack of information regarding doses ingested. Three other case series have further characterized the clinical manifestations of bupropion overdose (Table 2).

A retrospective case series of bupropion ingestions reported to five regional poison centers from 1989 to 1991 identified 58 bupropion-only

ingestions, all involving immediate-release formulation [16]. The mean toxic dose producing seizure was 3,078 mg. Seizures occurred in 12 of 58 (21%) patients, with a mean time to onset of 3.7 h. Among patients who seized, the dose ranged from 575 mg to 6,000 mg, and two of 12 patients who seized had multiple seizures. Other neurologic symptoms included lethargy, tremor, confusion, hallucinations, and paresthesias [16].

A subsequent retrospective case series from the Texas Poison Center Network identified 358 cases of bupropion overdose from 1998 to 1999 [17], the majority of them involving sustained-release formulations. Seizures occurred in 41 of 358 (11%) patients, with doses ranging from 600 mg to 18,000 mg, and a time to seizure onset ranging up to 14 h. Multiple seizures were documented in 9 of 41 patients. Two deaths were reported, although in one case it was difficult to definitively ascribe death to bupropion, because of co-ingestants [17].

A final case series identified 117 overdoses of extended-release bupropion [18]. Seizures developed in 37 of 117 (31.6%) patients, 18 of whom had multiple seizures. In some instances, seizure onset was delayed up to 24 h post-ingestion. The range of ingested doses was 600 mg to 54,000 mg,

with an average dose of 4,350 mg. Other clinical effects included tremor, agitation, and tachycardia. The sole reported death in this study was a 16-month old who ingested 143 mg/kg of bupropion and developed multiple seizures, followed by ventricular fibrillation and cardiac arrest [18].

Cardiovascular Toxicity

Sinus tachycardia is the most common cardiac finding in bupropion overdose [16–18]; however, several case reports describe QRS widening and QT interval prolongation [11, 19–23]. While many cases are obfuscated by co-ingestants or lack of serum bupropion concentrations, one case report in which serum bupropion concentrations were measured demonstrated that the QRS widening and QT interval prolongation coincided with the peak concentration of the parent compound and that these findings normalized once bupropion concentrations fell [11]. QRS widening is not due to cardiac sodium channel blockade, which explains why sodium bicarbonate fails to reliably influence QRS width in case reports [11, 19, 21]. Rather, bupropion is believed to widen the QRS by inhibiting intercellular gap junctions, which normally allow electrical communication between myocytes allowing for propagation of excitation [7]. The clinical significance of QT interval prolongation due to bupropion is unknown; to date, no cases of Torsades de Pointes have been reported, despite reports of QT intervals up to 600 ms [22, 23]. A prospective case series found that 13 of 17 patients with bupropion overdose had a QTc interval exceeding 440 ms; however, no arrhythmias were reported. The investigators postulated that the prolonged QT interval was not due to cardiac disease but rather formulaic overcorrection due to tachycardia [23]. In severe cases, patients can present with cardiogenic shock with global cardiac dysfunction [20] and in some cases cardiac arrest [21].

Brain Death mimic

Rare case reports describe bupropion overdose mimicking brain death [24, 25]. One case report

described a 29-year-old woman with fixed, dilated pupils, absent brain stem reflexes, no spontaneous respiration, and a burst suppression pattern on EEG. Not initially recognized as an overdose, these findings resolved completely within 36 h of presentation [25]. In patients exhibiting such findings in the setting of possible bupropion overdose, sufficient time for drug clearance should be afforded prior to declaration of brain death.

Death

Although deaths were uncommon in the case series noted above [17, 18], fatalities from bupropion overdose have been reported. A series of five fatalities documented serum bupropion concentrations ranging from 3.1 to more than 20 mg/L, with four patients having ingested the extended-release formulation [26]. This series also identified retained pill fragments in the stomach of four patients on autopsy. In light of very elevated bupropion concentrations, it has been postulated that these may represent “ghost pills” from which the active compound had been released, leaving only residual matrix behind [26].

Recreational Abuse and Misuse

Recreational abuse of bupropion is a relatively new but growing phenomenon. Bupropion has amphetamine-like properties and is easily obtained by patients under the pretense of seeking an antidepressant or smoking cessation aid [27, 28, 29]. People who misuse bupropion report experiencing a mild cocaine-like “high” [27, 29]. Reported routes of misuse include oral [30], intravenous [27, 28, 31], and nasal insufflation [29, 32–37]. A recent case series involving 67 cases of bupropion insufflation reported to the California Poison Control System identified 20 patients who experienced seizures but none with a second or delayed onset seizure [38]. The lack of delayed or multiple seizures, as often seen following oral bupropion overdose, reflects disruption of the modified-release formulations intended to slow gastrointestinal absorption.

Consequently, patients who abuse bupropion via non-oral routes may not require the same duration of monitoring as those who ingest large amounts. Other adverse effects resulting from non-oral administration include dramatic tissue necrosis and secondary infections [27], as well as epistaxis following insufflation [29]. These can represent clinical clues of misuse in the appropriate context.

Bupropion abuse has also been identified as a growing problem in correctional facilities [39]. Some users report first learning to misuse bupropion while incarcerated [29, 39]. Additionally, Internet forums exist, providing instruction on recreational misuse of bupropion [28].

Diagnosis

Bupropion overdose is a clinical diagnosis based on a history of exposure in the context of corresponding symptoms and signs. Given the drug's widespread availability, bupropion toxicity should be suspected in patients with otherwise unexplained seizures. Although serum bupropion concentrations have been measured in case reports, they are not readily available in most settings and unlikely to aid in management. Urine immunoassays do not detect bupropion *per se*, but given its phenylethylamine skeleton, false-positive screens for amphetamine can serve as a potential clue to bupropion toxicity [16, 22].

In addition to a history of new-onset seizures, other relevant associated signs include tremors, agitation, and hallucinations. While these findings may presage seizures [16–18], patients with bupropion toxicity may seize despite the absence of such features [18].

Patients with bupropion toxicity can range from lucid to seizing or post-ictal and can even display features suggestive of brain death [24, 25]. The presence or absence of tachycardia is helpful, as case series demonstrate that nearly all patients with bupropion-induced seizures were tachycardic [16–18]. Given the risk of seizures and the associated complications, the authors

recommend a low threshold for mechanical airway protection in all cases. Other aspects of the physical examination that may provide clues to abuse include a nasal airway exam to identify bleeding or injury from insufflation, as well as a dermatologic exam looking for track marks at injection sites or evidence of ulcers, tissue necrosis, or cellulitis [27, 29].

The presence of QRS widening and/or QT interval prolongation, particularly in the absence of other contributing causes, should raise the possibility of bupropion toxicity, particularly when a urine drug screen is positive for amphetamine. In a series of more than 10,000 urine drug screens obtained from emergency department patients, 362 tested positive for amphetamine using the EMIT II assay. However, in 128 (35%) of cases, no amphetamine was detected on gas chromatography. In nearly half of such cases, records documented bupropion use only [40].

Treatment

The treatment of bupropion overdose is primarily supportive. Treatment recommendations are informed by available case series rather than by high-quality evidence.

Supportive Care

Patients with suspected bupropion overdose should be cared for in a monitored setting, with particular attention to neurologic and cardiovascular status. Due to the delayed presentation of seizures, the authors recommend that patients suspected of bupropion overdose – especially those with ingestions of modified-release formulations – be monitored for a minimum of 24 h (Grade III recommendation).

In addition to routine investigations and telemetry, serial electrocardiograms are advisable, particularly following large ingestions and those in which QT prolongation or QRS widening are anticipated. As described above, a false-positive

urine drug screen for amphetamines may reflect the presence of bupropion.

Decontamination

In patients with bupropion overdose who present to hospital within 2 h of ingestion, the authors recommend the administration of activated charcoal (1 g per kilogram) (Grade III recommendation). However, due to variability in gastric emptying time, amount ingested, and potential co-ingestions, no absolute cut-off time can be recommended for activated charcoal. Although no data demonstrate that activated charcoal improves clinical outcomes in patients with bupropion overdose, it is a relatively safe intervention expected to reduce bupropion absorption. The primary hazard associated with activated charcoal is pulmonary aspiration. As such, in patients with mental status alterations or seizure, it should only be given once the airway has been secured and nasogastric tube placement confirmed [41] (Grade III recommendation).

Gastric emptying procedures are not indicated, and induction of emesis is absolutely contraindicated given the high risk of aspiration in the event of seizure. Some authorities recommend whole bowel irrigation for large ingestions of modified-release pharmaceuticals, based primarily on volunteer studies involving subtoxic ingestions [42]. Whole bowel irrigation is potentially useful only in patients with large ingestions of modified-release bupropion whose airway is mechanically protected and who display no evidence of ileus, perforation, or mechanical obstruction (Grade III recommendation).

Seizure Management

Case series suggest that benzodiazepines are effective in the management of bupropion-induced seizures [16–18] and are indicated as first-line therapy (Grade III recommendation). Phenytoin is unlikely to terminate toxicant-induced seizures (see ► Chap. 20, “Toxicant-

Induced Seizures”). A murine model found that phenytoin, carbamazepine, and lamotrigine all failed to block the convulsant effects of bupropion [43]. Barbiturates (phenobarbital, pentobarbital, and thiopentone) are superior to phenytoin as second-line therapy in animal models [44]. The roles of propofol or levetiracetam in bupropion overdose are unclear, although propofol’s GABA agonist effects may allow synergy with benzodiazepines and barbiturates in refractory cases [44]. For seizures refractory to benzodiazepines or in patients with recurrent seizures, barbiturates or propofol are indicated as second-line therapy (Grade III recommendation). There is no justification for prophylactic anticonvulsant therapy in patients with bupropion poisoning.

Cardiovascular Support

Conduction Abnormalities

Despite the electrocardiographic features of bupropion toxicity, sodium bicarbonate is unlikely to attenuate bupropion-induced QRS widening. In the absence of another indication, its use is not indicated (Grade III recommendation). The clinical significance of QT prolongation due to bupropion is unknown and there is no specific treatment in this scenario other than addressing other factors that may be contributing to QT prolongation. There is no evidence to support prophylactic magnesium unless deficient.

Cardiovascular Instability

In patients with significant cardiovascular instability (including cardiogenic shock and arrest), case reports describe the successful use of lipid emulsion [21]. We recommend lipid emulsion therapy be administered in the setting of significant cardiovascular instability (Grade III evidence), ideally after consultation with a medical toxicologist. Three case reports (one involving an infant [45] and two involving teens [46]) describe the successful use of extra-corporeal membrane oxygenation following massive bupropion

overdoses presenting with refractory cardiogenic shock and seizures. These therapies should be considered as adjuncts to standard advanced cardiovascular life support (ACLS) care (Grade III recommendation).

Treatment Recommendations:

Supportive Care

- Monitor for a minimum of 24 h in cases of oral ingestion. Prolonged monitoring is not required when injected or crushed and insufflated.

GI Decontamination

- Activated charcoal is potentially of benefit for patients presenting within 2 h of ingestion provided their airway is mechanically protected (longer for patients with very large ingestions)
- Whole bowel irrigation is possibly of benefit for patients with large ingestions of modified-release formulations with a mechanically protected airway. Contraindications to WBI include ileus, perforation, or mechanical obstruction.
- Gastric lavage is not recommended.

Seizures

- Benzodiazepines are first-line therapy for seizures.
- Barbiturates or propofol are second-line therapy for refractory seizures.
- Phenytoin is not recommended for treatment of bupropion-induced seizures.

Cardiac

- Sodium bicarbonate is unlikely to be effective if QRS widening from bupropion is noted and is not recommended in the absence of other indications.
- In the setting of cardiogenic shock or cardiac arrest refractory to standard ACLS, lipid emulsion therapy is recommended as adjunct treatment.
- In the setting of cardiogenic shock or cardiac arrest refractory to above therapies, extra-corporeal membrane oxygenation is recommended as adjunct treatment.

Key Points

- Bupropion abuse and overdose are increasingly common.
- Routes of abuse include oral, nasal insufflation, and intravenous injection.
- Seizures are the hallmark of neurotoxicity, and presentation can be delayed up to 24 h post-ingestion of modified-release formulations.
- Sinus tachycardia is the most common cardiac manifestation of bupropion overdose.
- QRS widening and QT interval can also be seen. Despite ECG pattern suggesting sodium channel blockade, sodium bicarbonate therapy is unlikely to be effective for the treatment of widened QRS due to bupropion toxicity. No cases of Torsades de Pointes have been reported to date.
- Benzodiazepines are first-line agents for treatment of seizures. Barbiturates or propofol would be appropriate second-line agents.
- Evidence for lipid emulsion and ECMO is extremely limited, but a trial is warranted in patients with severe, refractory cardiovascular toxicity.

The use of the cyclic antidepressants (CAs) in the treatment of major depression has decreased as newer and safer antidepressants have become available. Cyclic Antidepressants historically have been primarily used to treat major depression but are still prescribed for other psychiatric and medical conditions, such as chronic pain syndromes (e.g., fibromyalgia), peripheral neuropathy, nocturnal enuresis, migraine headache, selected drug withdrawal syndromes, and obsessive-compulsive, attention-deficit, panic and phobia, anxiety, and eating disorders [1, 2]. The CAs are associated with a low therapeutic index, potential severe cardiotoxicity in overdose, and a high frequency of adverse effects secondary to their nonspecific pharmacologic actions. Although CA use is less than it once was, the CAs remain on the 2014 American Association of Poison Control Centers' list of Top 25 Categories of Substances associated with fatalities [1, 3].

Currently available CAs are listed in Table 1. The three most commonly reported CAs involved in reported drug exposures in the United States are amitriptyline, doxepin, and nortriptyline [3, 4]. Outside of the United States, other CAs (e.g., dothiepin and clomipramine) may be seen more commonly in overdose [5–8]. Two other CAs, maprotiline and amoxapine, have minor structural differences compared with traditional CAs but have similar toxicity in overdose.

Toxicity from CAs most commonly occurs following an acute intentional overdose. However, there are multiple ways by which CAs may

Table 2 Mechanisms for cyclic antidepressant drug toxicity at therapeutic doses

Combination medications containing other active ingredients (e.g., antipsychotics)
Development of serotonin toxicity
Elevated plasma concentrations of CAs due to genetically based slow hepatic metabolism
Exacerbation of preexisting cardiovascular or central nervous system (CNS) disease
Pharmacokinetic drug interactions with medications that inhibit hepatic metabolism
Pharmacodynamic drug interactions with medications sharing similar pharmacologic actions
Unacclimated (i.e., CA-naïve) individuals started on high initial doses

CA cyclic antidepressant

produce mild-to-moderate clinical toxicity when administered in therapeutic doses (Table 2). First, the average therapeutic dose of CAs is highly variable. In general, low doses are used initially, followed by gradual increases until the desired therapeutic response is achieved. This approach allows patients to become acclimated to the potential adverse effects. Patients started at higher initial doses are more likely to develop such adverse effects. Second, toxicity can result when CAs are combined with other medications having similar pharmacologic actions (e.g., antihistamines, antipsychotics) [9]. Third, a subset of the population consists of poor metabolizers of CAs due to CYP2D6 polymorphism, and these individuals

develop higher plasma CA concentrations at any given dose [10, 11]. Fourth, many drugs have the potential to inhibit the metabolism of CAs, resulting in elevated CA plasma concentrations [10]. Fifth, some CAs are available as mixed-drug formulations combined with either benzodiazepines or antipsychotic agents and have the potential for combined drug toxicity. Sixth, patients with certain medical conditions, such as underlying cardiac problems or seizure disorder, are more susceptible to CA toxicity at therapeutic doses [10]. Finally, CAs have the potential to produce serotonin toxicity, especially when taken concomitantly with other serotonergic medications (see ► Chap. 24, “Serotonin Syndrome”).

Biochemistry and Clinical Pharmacology

The CAs have a distinct chemical structure comprising three aromatic rings: a central seven-member ring, two outer benzene rings, and an aminopropyl side chain connected to the central ring (Fig. 1) [1]. There are only minor structural differences among the CAs, usually on the central aromatic ring or aminopropyl side chain. Amoxapine is unique in that it has an aromatic substituent. Maprotiline has an ethylene bridge across a six-member center ring, giving it a tetracyclic chemical structure. Other chemicals

Diphenhydramine
Phenothiazines
Quetiapine

that share the same basic tricyclic chemical structure as the CAs produce similar toxicity in overdose and may trigger a false-positive CA plasma or urine drug screen (Table 3) [12–15].

Pharmacokinetics

All CAs share similar pharmacokinetic properties [10]. They are highly lipophilic and easily cross the blood–brain barrier. Peak plasma levels occur between 2 and 6 h after ingestion at therapeutic doses. Gastrointestinal absorption may be prolonged because of their antimuscarinic effect on gut motility. Bioavailability is only 30–70% because of extensive first-pass hepatic metabolism. They are highly protein bound to α_1 -acid-glycoprotein. Their apparent volume of distribution is extremely large (range 10 to

50 L/kg). Tissue CA levels are commonly 10–100 times greater than plasma levels [10]. Only 1–2% of the total body burden of CAs is found in the blood [16]. These pharmacokinetic properties explain why attempts at removing CAs by hemodialysis, hemoperfusion, peritoneal dialysis, or forced diuresis are ineffective [16].

Pharmacokinetics of Cyclic Antidepressants

Volume of distribution: large

Gastrointestinal absorption: rapid

Bioavailability: 30–70%

Peak blood levels: 2–6 h after ingestion

Protein binding: highly protein bound

Half-life: ranges from 24 to 48 h

Method of elimination: eliminated by hepatic metabolism using CYP-450 system

Active metabolites: some CAs have active metabolites

The CAs are eliminated almost entirely by hepatic oxidation, which consists of *N*-demethylation of the amine side-chain groups and hydroxylation of ring structures (Fig. 2). The removal of a methyl group from the tertiary amine side chain usually produces an active metabolite designated by the *desmethyl*- (or *nor*-) prefix. These active metabolites often have different pharmacologic activities compared with the parent compounds.

Fig. 2 Structural depiction of the metabolic pathways of imipramine. These metabolic transformations are also typical of other cyclic antidepressants

Amoxapine and maprotiline have active metabolites. Although secondary amines, such as desipramine, nortriptyline, and protriptyline, are effective antidepressants, their metabolites are generally inactive. Clinical toxicity from tertiary CAs usually lasts longer than toxicity from the secondary CAs alone because of the production of active metabolites. Some CAs undergo enterohepatic circulation before their eventual oxidation, conjugation, and renal elimination, but this does not contribute significantly to their toxicity. The average elimination half-life of CAs is approximately 24 h (range 6–36 h) at therapeutic doses, which can increase to 72 h after overdose. As previously noted, inhibition of CA metabolism by other drugs that use the same hepatic enzymes can prolong the half-life of CAs; this carries the risk of elevating CA plasma concentrations and producing clinical CA toxicity at therapeutic doses.

Pathophysiology

The CAs are nonselective agents that exhibit a multitude of pharmacologic effects (Table 4). There are subtle and potentially clinically significant pharmacologic differences among the CAs at therapeutic plasma concentrations. These differences become less important, however, at the higher plasma levels typically associated with overdose. Only a few of the pharmacologic actions of the CAs are believed to have a direct therapeutic effect, among them inhibition of monoamine reuptake (norepinephrine, serotonin [5-hydroxytryptamine (HT)]) and antagonism of postsynaptic serotonin receptors (5-HT₂) [7, 16]. The remaining pharmacologic actions essentially have no therapeutic benefit but contribute significantly to CA-related adverse effects and overdose toxicity. Most of the clinical findings seen in CA

^aListed in descending order of potency

overdose can be explained by the following pharmacologic actions.

Antihistaminic Effects

The CAs are potent inhibitors of peripheral and central postsynaptic histamine receptors [7]. Doxepin is a particularly potent antihistamine, but its nonspecific pharmacologic activity makes it impractical to use for treatment of seasonal allergies or other allergic conditions. Antagonism of central histamine receptors primarily leads to sedation and may contribute significantly to the development of coma and seizures frequently seen in CA overdose.

Anticholinergic (Antimuscarinic) Effects

CAs frequently produce anticholinergic effects [7]. They are competitive inhibitors of acetylcholine at central and peripheral muscarinic receptors. Antimuscarinic is therefore a more precise term because CAs are not antagonists at nicotinic receptors. Central antimuscarinic signs and symptoms vary from agitation to delirium, confusion, amnesia, hallucinations, slurred speech, ataxia, sedation, and coma. Peripheral antimuscarinic manifestations are primarily comprised of dilated pupils, blurred vision, tachycardia, hyperthermia, hypertension, decreased oral and bronchial secretions, dry skin, ileus, urinary retention, increased muscle tone, and tremor. Antimuscarinic signs and

symptoms are exacerbated when CAs are combined with other medications that possess antimuscarinic activity. Examples of such medications include antihistamines, antipsychotics, antiparkinsonian drugs, antispasmodics, and some muscle relaxants.

Physostigmine is an inhibitor of acetylcholinesterase and can reverse antimuscarinic toxicity. Historically, physostigmine was used to reverse CA-induced antimuscarinic effects, but its use was thought to be associated with life-threatening complications [17]. Although antimuscarinic clinical manifestations are a common occurrence in CA overdose, they are not directly responsible for CA-related major toxicity or deaths. Antimuscarinic effects are an important clinical marker of CA toxicity, but they do not require specific therapy other than supportive care. Physostigmine is not indicated in the current management of CA overdose [18].

Antagonism of α -Adrenergic Receptors

Inhibition of postsynaptic central and peripheral α -adrenergic receptors, but not β -adrenergic receptors, is characteristic of most CAs [7]. CAs have a much greater affinity for α_1 -adrenergic than α_2 -adrenergic receptors [7]. Inhibition of α_1 -receptors results in CNS sedation, orthostatic hypotension, reflex tachycardia, and pupillary constriction. This action frequently offsets antimuscarinic-induced pupillary dilation. Patients with CA toxicity can present with constricted, dilated, or midpoint-sized pupils.

Inhibition of Amine Reuptake

Inhibition of monoamine reuptake is believed to be the most important mechanism by which CAs are efficacious in the treatment of depression. CAs are potent inhibitors of norepinephrine and 5-HT reuptake, but they have little affinity for inhibition of dopamine reuptake [7]. Inhibition of neurotransmitter reuptake leads to an increase in synaptic concentrations and subsequent augmentation of the neurotransmitter response. Inhibition of

norepinephrine reuptake is thought to produce the early sympathomimetic effects occasionally seen in some CA overdoses and may contribute to the development of cardiac dysrhythmias [16]. Serotonin toxicity results from increased 5-HT brainstem activity and has been produced by CAs that are particularly potent 5-HT reuptake inhibitors, such as clomipramine and amitriptyline [1]. In general, CAs must be combined with other serotonergic agents to produce serotonin toxicity. Myoclonus and hyperreflexia are signs of increased serotonin.

Sodium Channel Blockade

Cyclic antidepressant-induced cardiotoxicity is the most important factor contributing to patient mortality [6]. Life-threatening cardiotoxicity results from CA-induced inhibition of sodium influx through voltage-gated sodium channels. Inhibition of fast sodium channels in His-Purkinje cells leads to delayed depolarization and conduction abnormalities. Impaired sodium entry into myocardial tissue leads to decreased contractility. Sodium channel blockade, often referred to as a *membrane-stabilizing, quinidine-like, or local anesthetic effect*, results in a prolongation of phase 0 of the action potential. These effects become more pronounced with rapid heart rates, hyponatremia, and acidosis [19]. Sodium channel blockade is expressed on the electrocardiogram (ECG) as prolongation of PR and QRS intervals and right-axis deviation (RAD) of the terminal 40 msec [19]. The RAD is most pronounced in the terminal 40 msec of limb leads, as shown on the ECG by a terminal R wave in lead aVR and an S wave in lead I (see Figs. 21–15, 21–16, and 21–17). Rapid influx of sodium is necessary for the release of intracellular calcium stores and subsequent myocardial contractility. Some of the negative chronotropic effects of sodium channel blockade can be attenuated by sinus tachycardia secondary to antimuscarinic activity [19]. Local changes in electrical conduction can predispose to ventricular dysrhythmias by establishing reentry loops. Severe sodium channel blockade culminates in depressed

myocardial contractility, various types of heart block, hypotension, cardiac ectopy, and widening and RAD of the terminal 40 msec of the QRS complex.

Sodium channel blockade can be overcome in part by serum alkalinization (pH 7.45 to 7.55) and increasing the serum sodium concentration. In humans, intravenous sodium bicarbonate (NaHCO_3) is thought by some to be more effective than either hyperventilation (serum alkalinization) or intravenous sodium chloride in treating CA cardiotoxicity [20], but this has not been clearly established. One theoretical explanation for the postulated greater effectiveness of NaHCO_3 is that it produces both plasma alkalinization and increased serum sodium concentration [20]. The mechanism by which serum alkalinization partially reverses sodium channel blockade is unknown but currently is believed to be unrelated to enhancement of plasma CA serum protein binding (α_1 -acid glycoprotein), although it may involve reduced CA binding to the sodium channel [21]. Serum alkalinization is likely to result in a decrease in the overall inhibition of sodium ion influx. Animal data suggest that hypertonic saline (7.5% sodium chloride) may be as efficacious as NaHCO_3 in reversing CA cardiotoxicity [21]. Whether this finding also would be applicable to humans is currently unknown. Hypertonic saline is believed to act primarily by increasing the extracellular sodium concentration gradient, favoring the inward movement of sodium ions.

Potassium Channel Antagonism

Cyclic antidepressants block myocardial potassium channels and inhibit potassium efflux during repolarization [19]. This effect is seen on the ECG as QT interval prolongation, which is more pronounced at slower heart rates [21]. The extent of QT prolongation that is related to the inhibition of potassium efflux is hard to determine because the sodium channel effect is responsible for the broadening of the QRS complex, which by itself prolongs the QT interval. Many CA overdose patients develop sinus tachycardia, which is partially protective against QT interval prolongation.

Torsades de pointes (see ► Chap. 22, “Toxicant-Induced Torsade de Pointes”) is a potential life-threatening complication of severe inhibition of potassium efflux and delayed repolarization that is seen more commonly with therapeutic doses than with CA overdoses [22]. It is possible that the antimuscarinic-induced sinus tachycardia causes a relative narrowing of the QT interval and protection against torsades de pointes [19].

γ-Aminobutyric Acid A Receptor Antagonism

Generalized seizures occur in approximately 10% of CA overdoses [23]. Possible mechanisms for these seizures include CA-induced GABA_A receptor antagonism, neuronal sodium channel blockade, central anticholinergic activity, effects on biogenic amines, and antihistamine effect. As described below, benzodiazepines and barbiturates are potent GABA_A agonists and are considered the anticonvulsants of choice in treating CA-induced seizures [23]. Propofol is a short-acting intravenous anesthetic with anticonvulsant activity that may be utilized for patients with refractory seizures [24].

Clinical Presentation

Therapeutic doses of CAs are variable and are determined by many factors. In general, typical doses range from 1 to 5 mg/kg/day. Although some patients tolerate higher doses without adverse effects, doses greater than this have the potential to produce clinical toxicity. Life-threatening toxicity usually occurs with ingestions of greater than 10 mg/kg in adults [25]. Some patients are at greater risk for CA-related toxicity, including patients who have coingested cardiotoxic or CNS-depressive medications, geriatric patients, pediatric patients, and patients with heart disease. Cyclic Antidepressant-related toxicity is commonly associated with ingestions of greater than 1 g [25]. Most CA overdose fatalities occur within the initial hours after ingestion, often before the

patient reaches the hospital [26]. Fatalities are unusual for patients who are alive at the time of arrival to the hospital and receive appropriate care [27]. The mortality rate for hospitalized CA overdose patients is approximately 2% [27, 28]. The amount of CA ingested in most overdose cases is unknown. The diagnosis of CA toxicity should be suspected from a history of CA ingestion, clinical presentation consistent with CA toxicity, characteristic ECG abnormalities, or positive plasma CA drug screen.

Qualitative urine or plasma CA drug screens have high sensitivity but low specificity due to false positives (e.g., phenothiazines, carbamazepine). This aspect limits their utility in confirming the presence of CAs, but their low cost and rapid turnaround time also are occasionally beneficial. However, positive qualitative screens do not differentiate between therapeutic and toxic levels. Also, false-positive results are reported with medications that structurally resemble CAs (see Table 3) [12–16].

In contrast, quantitative determinations of plasma CA concentrations are specific for individual CAs and possess low false-positive rates. However, these tests are costly, time-consuming, and rarely clinically useful in the acute overdose setting [29, 30]. Quantitative assays are most useful for differentiating between therapeutic and toxic levels during long-term drug therapy (e.g., compliance, metabolism) [29, 30]. Furthermore, the results of quantitative assays are rarely available at the time of patient evaluation and have a negligible impact on patient care.

Some studies have shown that patients with a combined plasma concentration of parent CA and metabolite of greater than 1000 ng/mL are at greater risk for developing seizures and cardiotoxicity [29, 30]. The severity of clinical toxicity does not always correlate, however, with the extent of plasma CA concentration. Patients can develop severe toxicity at plasma concentrations less than 1000 ng/mL [29, 30]. Conversely, patients with plasma CA concentrations much greater than 1000 ng/mL may not develop seizures or ventricular dysrhythmias [29]. Serious toxicity rarely develops at therapeutic concentrations (<300 ng/mL). For

patients with plasma concentrations in this range, other causes should be considered to explain the patient's condition. As always, the primary focus should be on treating the patient, not the drug concentrations.

A unique characteristic of CAs is their ability to undergo significant postmortem drug redistribution [31, 32]. Plasma concentrations can increase by 10-fold to 50-fold after death as tissue binding sites release CAs, with resultant back diffusion into the blood as a time-dependent process. Theoretically, the accuracy of postmortem CA levels as a reflection of immediate antemortem levels is related inversely to the time interval between death and subsequent specimen collection. Elevated CA concentrations that are obtained after death may be assigned inappropriately as the cause of death, when they simply reflect therapeutic body burdens that have undergone redistribution. Unless this possibility is recognized, it may raise false concerns about the care provided to the patient during his or her hospitalization or a misclassification of the cause of death to drug toxicity or overdose.

Clinical Manifestations of Acute Overdose

Signs and symptoms typically develop within the first few hours after ingestion [33]. The clinical presentation of CA toxicity varies from mild antimuscarinic symptoms to coma and severe cardiotoxicity. Another consideration is that CA ingestions often involve coingestion of other drugs which can produce additional toxicity. Patients who do not manifest significant toxicity (Table 5) by 6 h postingestion are considered at low risk for life-threatening complications. The most frequently reported effects are CNS sedation and sinus tachycardia. Along with other antimuscarinic effects, these effects serve as clinical markers of CA toxicity, but alone they are rarely responsible for fatalities. Antimuscarinic effects are not uniformly present in CA toxicity [25]. The antimuscarinic syndrome is classically associated with diminished bowel sounds and ileus. Gut function is fairly resistant to this effect,

Table 5 Major toxicity criteria following CA overdose

Seizures
Widened QRS complex >100 msec

however, and active bowel sounds can be present even in seriously ill patients. The presence of normal bowel sounds does not exclude the possibility of antimuscarinic syndrome.

Mild-to-moderate CA toxicity may present as drowsiness, confusion, slurred speech, ataxia, dry mucous membranes and axillae, sinus tachycardia, urinary retention, myoclonus, and hyperreflexia. Central nervous system depression is often associated with respiratory depression leading to hypoxia or aspiration or both. Many CA overdose patients require endotracheal intubation to manage their respiratory depression and loss of airway protection. Mild hypertension is observed occasionally and rarely requires treatment. Nontolerant individuals (e.g., young children) frequently develop coma and respiratory depression after relatively small overdoses without obvious peripheral antimuscarinic effects and without QRS widening [34]. Overflow urinary incontinence may be mistaken for normal micturition in pediatric (diaper-dependent) patients.

Serious toxicity almost always is seen within 6 h of major CA ingestion and consists of coma, cardiac conduction delays, wide-complex supraventricular tachycardia, hypotension, respiratory depression, premature ventricular beats, ventricular tachycardia, and seizures [4, 25, 28, 33, 34]. Secondary complications from serious toxicity include aspiration pneumonia, anoxic encephalopathy, hyperthermia, and rhabdomyolysis [25]. The acute respiratory distress syndrome is a well-recognized complication of CA overdose [35]. Seizures usually are generalized and brief and occur in roughly 10% of patients [23]. The risk of seizures increases as the QRS complex exceeds 100 msec. The exception to this rule is seen in amoxapine and maprotiline overdoses,

Fig. 3 Electrocardiogram (ECG) from a 39-year-old man after a tricyclic antidepressant overdose. The ECG shows signs of impaired conduction in the His-Purkinje system: QRS widening greater than 100 msec and rightward

deviation of the terminal 40-msec frontal plane QRS vector (aVR). In the presence of tricyclic antidepressant overdose, these ECG findings suggest significant cardiotoxicity

which have been reported to cause status epilepticus [6]. Amoxapine-induced seizures commonly occur without corresponding QRS widening [6].

Electrocardiogram abnormalities are almost always seen with significant CA toxicity and are extremely useful in identifying patients at increased risk for seizures and ventricular dysrhythmias [36, 37]. A QRS duration of greater than 100 msec and 160 msec following overdose is associated with approximately 33% chance of developing seizures and 50% chance of ventricular dysrhythmias, respectively [37]. The “classic” CA ECG, shown in Figs. 3, 4, and 5, consists of sinus tachycardia; RAD of the terminal 40 msec (best seen as a terminal R wave in lead aVR); and prolongation of the PR, QRS, and QT intervals (Table 6). This classic ECG pattern is seen frequently in moderate-to-severe CA toxicity [36], but the absence of these findings does not eliminate the possibility of CA toxicity during the first 6 h after ingestion [29, 30]. Moderate prolongation of the QT interval is noted frequently even at therapeutic CA doses. Nonspecific ST-segment and T-wave abnormalities are observed commonly in CA overdose. High-degree atrioventricular blocks are less commonly reported [36]. These reports

probably reflect the ECG similarities between CA effects and right bundle-branch block [38].

Life-threatening complications can occur in the absence of significant ECG abnormalities [30]. These complications are far more likely, however, in the presence of a QRS interval greater than 100 msec or RAD of the terminal 40 msec greater than 120° [29, 30, 36]. Wide-complex tachydysrhythmias are more likely if QRS prolongation exceeds 160 msec. Widening of the QRS complex and positive deflection of the terminal QRS complex in lead aVR are similar in identifying patients at risk for serious CA toxicity [36]. They usually occur together but may occur in the absence of each other. The development of RAD of the terminal 40 msec or QRS widening seems to be less predictive of CA-induced cardiotoxicity in young children [36]. Pediatric ECGs tend to have a wider range of acceptable variant features including a natural rightward axis, and this complicates the ECG identification of CA toxicity in children [36].

Electrocardiographic abnormalities, if they are to occur, universally develop within 6 h of ingestion and typically resolve over 24–48 h [39]. A subset of the normal population may have a QRS duration of more than 100 msec or terminal RAD

Fig. 4 Electrocardiogram (ECG) from a 39-year-old man after a tricyclic antidepressant overdose (Fig. 3) was the presenting ECG. ECG changes associated with progressively impaired conduction in the setting of an untreated tricyclic antidepressant overdose are shown. QRS width was 120 msec in the *upper* strip, which was recorded after the patient had his first seizure. The *middle* strip reveals a

QRS of 160 msec and was recorded 134 min later, immediately after the second seizure. The *lower* strip was recorded 60 min later, after the fourth seizure, in the radiology suite where the patient was undergoing a cranial computed tomography scan. Subsequently the patient experienced a cardiac arrest, and efforts at resuscitation were unsuccessful

Fig. 5 A positive deflection greater than 3 mm of the terminal portion of lead aVR (R'), frequently called a *terminal R*, is a significant predictor of seizures or arrhythmias in tricyclic antidepressant poisoning. Similar intraventricular conduction delay suggests presence of a fast sodium channel blocker in a poisoned patient

without exposure to sodium channel-blocking drugs; this includes individuals with a right bundle-branch block. These ECG abnormalities in isolation are not specific for CA toxicity. Many patients receiving CA therapy do not have prior ECGs available for comparison. Any observed ECG abnormalities initially should be assumed attributable to CA exposure until proven otherwise.

Diagnosis

Cyclic antidepressant toxicity should be suspected in all patients following overdose with clinical toxicity or characteristic ECG abnormalities or both (see Table 6). The differential diagnosis of CA toxicity encompasses drugs that can

Table 6 Classic electrocardiographic abnormalities in cyclic antidepressant toxicity

Sinus tachycardia
Prolonged PR interval
Prolonged QT interval
Widened QRS complex >100 msec
Right-axis deviation (positive deflection) of terminal QRS complex in lead aVR >3 mm

mimic any one of the three criteria used in making the diagnosis. A urine toxicology screen or serum drug concentration may be useful in confirming the diagnosis but is generally unnecessary and false negatives may occur in early presenters who have not had significant excretion of CA. The best screening diagnostic test for CA toxicity is the ECG because most CA-poisoned patients manifest major toxicity within 2 h of ingestion or not at all. The combination of characteristic ECG changes and typical manifestations of toxicity is a sensitive and a specific approach to the diagnosis of poisoning by these agents [38].

Treatment

All patients should be evaluated immediately for alteration of consciousness, hemodynamic instability, and respiratory impairment. Every patient requires prompt placement of an intravenous line, continuous cardiac monitoring, and a 12-lead ECG. Serial ECGs may be required in patients manifesting any signs of toxicity. Suggested laboratory studies include determinations of serum electrolytes, creatinine, and glucose concentrations. A quantitative serum acetaminophen level is indicated in all intentional overdose patients. Patients with antimuscarinic signs (i.e., abdominal distension and inability to void) may require a urinary catheter to treat urinary retention. Patients who are initially asymptomatic may deteriorate rapidly and should be monitored closely for several hours (Grade II-2 – III recommendations) [22, 23].

Gastrointestinal Decontamination. Although the best method of gastrointestinal decontamination in CA ingestions is unknown, a few generalizations are supported by available evidence [40]. Activated charcoal has been shown to bind

CAs effectively and reduce their absorption [41]. Most patients who have ingested a CA within the previous few hours should receive 1 g/kg of activated charcoal [42] (Grade III recommendation); however, the airway should be adequately protected before activated charcoal administration. Patients who have ingested an overdose of CAs may have sudden deterioration in their mental status and may aspirate if their airway is not protected. Activated charcoal has not been shown to improve outcome after CA overdose. If activated charcoal is given, it should be administered as a single dose.

Serum Alkalinization and Sodium Bicarbonate Therapy. As described earlier, theoretical rationale and empirical data support serum alkalinization and the administration of sodium for the treatment of CA toxicity with widened QRS complexes. This treatment can be achieved either by ventilator-driven hyperventilation with intravenous saline and by the administration of bolus 1 molar (8.4%) NaHCO_3 . QRS widening greater than 100 msec warrants bolus NaHCO_3 therapy and admission to a monitored hospital bed [32]. Patients with a decreased level of consciousness should be treated with mechanical ventilation and induced respiratory alkalosis, with the aim of keeping the serum pH between 7.5 and 7.5. Any hemodynamic deterioration, seizures, or sudden further widening of the QRS complex can be treated with bicarbonate boluses. If multiple repeated boluses of sodium bicarbonate are administered, serum sodium and pH should be monitored.

Indications for ventilator-driven serum alkalinization/ saline or NaHCO_3 therapy include QRS complex duration greater than 100 msec and ventricular dysrhythmias (Table 7) (Grade II-3 – III recommendations) [16, 18, 20]. Intravenous NaHCO_3 and an increase in serum pH have been shown to improve conduction, increase contractility, and suppress ventricular ectopy (Grade II-3 recommendation) [20]. Because of the potential for cardiogenic pulmonary edema and acute lung injury in CA-toxic patients, it is important to reduce the rate of fluid administration when the patient is stabilized. Potential complications of intravenous NaHCO_3 therapy include

Table 7 Indications for serum alkalization in cyclic antidepressant toxicity^a

Terminal right-axis deviation (positive deflection) in lead aVR >3 mm
Ventricular dysrhythmias
Widened QRS complex >100 msec

^aWith induced hyperventilation or sodium bicarbonate administration. See text for details

hypokalemia, hypercapnia, hypotension, prolongation of the QTc interval, and intracellular acidosis [43]. Serum potassium concentrations should be measured frequently, and potassium supplementation should be administered to maintain the serum potassium concentration above 4.0 mEq/L. Induced hyperventilation is performed by inducing a respiratory alkalosis with the targeted end point being a pH range similar to that described earlier.

Intravenous Fat Emulsion. Intravenous fat emulsion (IFE) as an antidote for the treatment of poisoned patients appears to be gaining popularity recently [44]. Possible mechanisms of action of IFE include the creation of an intravascular “lipid sink” to sequester drug, improvement in fatty acid utilization to serve as an alternative fuel source, a direct cardiostimulant effect to improve hemodynamic status, and modulation of ion channels [44]. There are some animal and human data to support the beneficial effect of IFE to improve hemodynamic status and survival in the setting of CA toxicity [45–48]. However, due to the historic efficacy of sodium bicarbonate, additional study is needed before IFE can be recommended as antidotal therapy for CA toxicity at this time.

Altered Level of Consciousness

In general, patients with an altered level of consciousness should be assessed for hypoglycemia and intravenous dextrose should be administered if glucose is determined to be low. Intravenous thiamine and oxygen can be routinely given to almost all patients with a depressed mental status and if concern for chronic alcohol abuse. Naloxone may be given if there are signs of the opioid toxidrome. Antagonism of postsynaptic

muscarinic, histaminic, and α -adrenergic receptors may contribute to the development of altered mentation in CA overdoses. It is possible that other direct CNS effects unrelated to these mechanisms may occur. Coma from CA toxicity typically occurs rapidly. Unresponsive patients may have unrecognized head or neck trauma. Flumazenil should not be given to patients suspected of CA overdose because this may precipitate generalized seizures (Grade III recommendation) [42]. Agitation may be seen in previously comatose patients as they awaken. Agitation is best controlled with reassurance, decreased environmental stimulation, and benzodiazepines. As mentioned previously, physostigmine plays no role in the management of CA poisoned patients.

Seizures

Most seizures occur within the first 2 h after CA ingestion. Typically, these seizures are generalized and brief and commonly do not require anticonvulsant therapy [23]. Multiple seizures are reported in less than 10% of CA overdoses [18, 23]. Focal seizures are atypical and require further neurologic evaluation. Seizures are more common with maprotiline and amoxapine ingestions and require aggressive management because status epilepticus is associated more frequently with these two particular antidepressants [24]. Benzodiazepines (e.g., diazepam, lorazepam) are the anticonvulsants of choice for ongoing seizure activity (Grade III recommendation) [23]. Barbiturates (e.g., phenobarbital) are indicated in the treatment of recurrent seizures or seizures resistant to benzodiazepine therapy (Grade III recommendation). The initial intravenous dose of phenobarbital is 15 mg/kg given in 5-mg/kg increments, but this can be increased safely in patients with continued seizure activity who are not hemodynamically compromised. Because of the potential for inducing hypotension, the initial phenobarbital loading dose should be given in 5-mg/kg increments. Propofol also may be employed as second-line or third-line anticonvulsant therapy, but there is limited

clinical experience with this approach. If not already employed for CA-induced respiratory failure, endotracheal intubation and respiratory support are required when benzodiazepines are combined with barbiturates or propofol or when high doses of either of the latter are used (Grade III recommendation) [24].

If seizures continue despite adequate dosing with benzodiazepines, phenobarbital, and possibly propofol, the next step would be to paralyze the patient with a neuromuscular blocking agent (Grade III recommendation). This paralysis stops the physical manifestations of the seizure and its secondary effects, which include metabolic acidosis, hyperthermia, rhabdomyolysis, and renal failure. It does not stop brain seizure activity, however. After induction of muscle paralysis, these patients require electroencephalographic monitoring and further anticonvulsant therapy. (Toxicant-induced seizures are discussed in detail in ► Chap. 20, “Toxicant-Induced Seizures”.)

Hypotension

Hypotension can be treated initially with isotonic crystalloid in increments of 10 mL/kg. In the setting of impaired cardiac contractility, pulmonary edema may develop if excessive fluids or NaHCO_3 is administered (Grade III recommendation). Vasopressors should be used when hypotension is unresponsive to fluid therapy (Grade III recommendation). Norepinephrine is believed to be the vasopressor of choice in the setting of CA-induced α -adrenergic blockade, but dopamine and epinephrine also have been shown to be effective (Grade II-2 – III recommendations) [39, 49, 50]. Severe CA-induced hypotension represents a potentially reversible cause of cardiovascular collapse. Mechanical support of the circulation with cardiopulmonary bypass, venoarterial extracorporeal membrane oxygenation, overdrive pacing, or aortic balloon pump assistance may be warranted in patients with refractory hypotension, although no studies adequately document their effectiveness (Grade III recommendation) [51, 52].

Dysrhythmias

Cyclic Antidepressants frequently alter cardiac rate, conduction, and contractility. Otherwise asymptomatic patients with sinus tachycardia, isolated PR and QT prolongation, or first-degree atrioventricular block do not require specific pharmacologic therapy. Conduction blocks greater than first-degree blocks can progress rapidly to complete heart block secondary to impaired infranodal conduction. Patients with isolated QRS duration greater than 100 msec may benefit from treatment with serum alkalization and NaHCO_3 therapy replacement, although this is controversial (Grade III recommendation) [20]. This recommendation is made despite the absence of randomized, controlled human trials showing NaHCO_3 therapy-related benefits in otherwise asymptomatic patients with QRS prolongation [20]. Nonetheless, the early use of serum alkalization with NaHCO_3 or induced hyperventilation in the setting of sodium channel blockade has become a common practice for treating QRS widening (Grade II-3 recommendation) [16].

Ventricular dysrhythmias should be treated immediately with molar NaHCO_3 bolus administration (Grade III recommendation) [16]. Lidocaine is the second agent of choice in treating ventricular dysrhythmias (Grade III recommendation) [16] although excessive lidocaine administration is capable of producing seizures. Synchronized cardioversion is appropriate in patients with unstable dysrhythmias. Torsades de pointes should be treated initially with at least 2 g of intravenous magnesium sulfate. Efforts should be made to rule out other causes of torsades de pointes. Overdrive pacing may be attempted to prevent recurrence of this dysrhythmia. Intravenous isoproterenol may be beneficial in treating recurrent torsades de pointes when overdrive pacing is not available. Treatment of torsades de pointes is discussed in ► Chap. 22, “Toxicant-Induced Torsade de Pointes.” The medications in Table 8 should be considered contraindicated in the treatment of torsades de pointes–induced dysrhythmias.

Table 8 Medications contraindicated in severe cyclic antidepressant overdose

Class Ia antidysrhythmics
Class Ic antidysrhythmics
Class III antidysrhythmics
β -Blockers
Calcium channel blockers
Flumazenil

Disposition

Patients who remain asymptomatic for at least 6 h after ingestion do not require hospital admission for toxicological reasons. They still may require hospital admission because of coexisting medical or psychiatric conditions. Psychiatric evaluation is warranted for intentional drug ingestions. All symptomatic patients require hospital admission to a monitored bed. Patients showing signs of moderate-to-severe toxicity should be admitted to an intensive care unit.

Indications for Emergency Department or ICU Admission in Cyclic Antidepressant Poisoning

All patients with evidence of moderate-to-severe CA toxicity require ICU admission.

Patients with mild toxicity can be admitted to a monitored bed.

Criteria for Emergency Department or ICU Discharge in Cyclic Antidepressant Poisoning

No clinical manifestation of toxicity after at least 6 h of observation, including normal vital signs

Normal or baseline electrocardiogram after 6 h of observation

Psychiatric evaluation completed in cases of intentional overdose

Nontoxic serum acetaminophen concentration (intentional overdoses)

Neurologic and pulmonary stability

Absence of antimuscarinic signs

Lithium salts, particularly lithium carbonate, are widely used to treat bipolar disorders. Although most literature cites the seminal article published in 1949 by the Australian psychiatrist Cade [1] as the initial study promulgating the efficacy of lithium salts in the treatment of mania, many earlier publications recognized its potential utility in the treatment of mood disorders, however. The Cade article, showing an attenuation of mania, followed his observation of a sedating effect of lithium on pigs. In a book by Hammond [2] published in 1871, lithium was recommended for the treatment of mania and depression. Similarly a publication by Lange in 1897, as described by Hanson and Amdisen [3], is reported to have promoted lithium's efficacy of the treatment of depression.

After the publication of the Cade article [1], lithium's use in the treatment of mood disorders became commonplace. Further studies on the use of lithium for bipolar disease were conducted in Europe, resulting in earlier widespread use of these salts there than in the United States [4]. The use of lithium salts in the United States lagged behind Europe because of many reports in the American literature in which the use of lithium as a salt substitute resulted in several deaths.

Along with the widespread use of lithium salts as a therapeutic agent, case reports were published describing significant toxic manifestations from this therapy associated with elevated serum lithium concentrations. El-Mallakh [5] described case reports of lithium toxicity dating back to 1948. In 1978, Hanson and Amdisen [3] described 100 case reports of lithium intoxication from the published literature dating back to 1949. There is little question that unmonitored lithium therapy, particularly in a susceptible patient, may result in toxicity.

Biochemistry and Clinical Pharmacology

Chemistry

Along with oxygen, lithium is the most chemically simple of all therapeutic agents, yet both have complex physiologic effects that are still

not fully understood. Lithium, from the Greek *lithos* meaning "stone," is in group 1A of the periodic table, situated immediately above sodium, providing an explanation for the similarity in behavior of these two ions. Lithium's atomic number of 3 means that it contains three electrons with a single unpaired one in its outermost shell. This outermost electron is ionized easily, creating the Li^+ ion. Lithium has an atomic weight of 6.9, and is therefore a light metal.

Because of the chemical similarities between lithium and sodium, lithium chloride has a salty taste. Starting in the late 1940s, lithium chloride was available in the United States as a salt substitute (West Sal). Ingestion of lithium chloride led to virtually immediate adverse effects [6, 7], some fatal, resulting in the regulatory actions taken in regard to lithium salts by the US Food and Drug Administration [8, 9].

Pharmacokinetics

Pharmacokinetics of Lithium

Volume of distribution: 0.7–1.4 L/kg

Therapeutic plasma concentration: 0.3–1.6 mmol/L

Protein binding: negligible

Plasma elimination half-life: 12–27 h*

Mode of elimination: renal

Method to enhance elimination: hemodialysis

*The half-lives given are for volunteers. Many factors, primarily therapeutic use (as opposed to overdose in a lithium-naïve patient), advanced age, and any decrease in renal clearance, may increase half-life.

Peak plasma lithium concentrations occur 30 min to 4 h after a dose, although this can be prolonged further in delayed-release preparations [4, 5, 10]. Liquid preparations are absorbed most rapidly. For standard lithium preparations, absorption is usually complete within 8 h [10]. When lithium is used therapeutically, target plasma concentrations vary from 0.3 to 1.6 mmol/L, depending on the indication. Lithium circulates as free Li^+ ion in

plasma without significant protein binding. Plasma elimination half-life in volunteers ranges from 12 to 27 h [11–13]. The apparent plasma elimination half-life is longer in patients with long-term lithium treatment, likely related redistribution Li^+ ions from tissue stores into plasma. This same phenomenon probably explains the slow excretion of lithium after its therapeutic use has been discontinued [14]. The half-lives in patients with lithium toxicity range from 12.9 to 50.1 h in different published series [15–17]. Although red blood cell (RBC) lithium concentrations may correlate with brain tissue lithium concentrations better than plasma lithium concentrations, quantification of RBC lithium does not offer clinical advantage over the combination of serum/plasma measurements and clinical exam [18].

Lithium elimination can be reduced dramatically in the elderly, most likely due to age-related reduction in creatinine clearance, and this population should be considered to be at particular risk for toxicity during therapeutic use. Lithium's serum half-life with therapeutic use has been reported to be 36 h in elderly patients [19, 20]. Similarly, any patient, regardless of age, with subnormal creatinine clearance or who are taking medications that decrease glomerular filtration, such as angiotensin-converting enzyme inhibitors and high-dose nonsteroidal anti-inflammatory drugs, should be considered to have at least a relative contraindication to lithium therapy.

When absorbed, lithium distributes to multiple tissues, with the most consequences in the brain, kidney, and thyroid [21, 22]. Tissue concentrations of lithium may continue to increase for hours after plasma concentrations have peaked, with its distribution through the blood–brain barrier into the brain being slower than into other organs [23]. This slow distribution phase probably accounts for the delayed onset of action and the delayed resolution of lithium-induced central nervous system manifestations after toxic exposure. Its volume of distribution is reported variously to be between 0.7 and 1.4 L/kg [24–26]. Lithium is found in the cerebrospinal fluid (CSF), although only at approximately 40% of plasma concentrations [27] because of its active

transport out of the CSF [28]. Lithium concentrations in both white- and gray-matter brain tissue approximate those in CSF [27].

Virtually all of an ingested lithium dose is excreted renally, with only trace amounts found in sweat, saliva, or breast milk. When filtered through the glomerulus, lithium and sodium are reabsorbed in the proximal tubule. Approximately 80% of the filtered lithium undergoes active reabsorption against an electrical and a chemical gradient in this segment of the nephron [4, 14, 29, 30]. Lithium is reabsorbed further in the loop of Henle [4]. In contrast to sodium, lithium is not reabsorbed in the distal tubule [31]. Lithium has a reported renal clearance of 13–56 mL/min [11, 12, 17, 29], and its fractional clearance (lithium clearance/creatinine clearance) has been reported to be 0.17–0.29 [12, 29, 32]. The renal clearance and fractional excretion of lithium decrease during hemodialysis [3]. In volunteer studies, lithium clearance can be increased by the administration of sodium chloride or bicarbonate, acetazolamide, urea, or aminophylline [29]. Neither water loading nor loop diuretics affect lithium clearance [29]. The small amount of lithium that is not eliminated renally is excreted in the feces and perspiration. Lithium exhibits a high clearance by conventional hemodialysis (100–150 mL/min) [3, 33]. Hemodialysis effectively removes only plasma lithium, and there is often a posthemodialysis “rebound” increase in serum lithium concentration as lithium diffuses down its concentration gradient from tissues into the plasma [3, 17, 34]. As expected, CSF lithium concentrations decrease during this redistribution phase [35, 36].

Pathophysiology

Central Nervous System Effects

The mechanism of lithium's mood-stabilizing effect is unknown and a matter of considerable debate. Lithium causes a variety of effects on neurons, although the exact contribution, if any, of these neuropharmacologic actions to its therapeutic effects is uncertain.

Lithium can enter the neuron via the fast sodium channel and stimulate an action potential. Unlike sodium, lithium is a poor substrate for the $\text{Na}^+\text{-K}^+$ pump, and no lithium-related electrochemical gradient across the cell membrane can be maintained. In theory, this causes intraneuronal lithium loading. How this loading might relate to the mood-stabilizing effects of lithium is unclear, however.

Lithium affects many enzymes and other proteins involved in neuronal and nonneuronal function and may modulate neurotransmission and central nervous system excitability. Neurons have many regulatory guanosine triphosphate-binding proteins, and lithium is known to inhibit their activities [37].

Research focusing on the molecular mechanism underlying the therapeutic effect of lithium has revealed that it induces changes in the activities of cellular signal transduction systems, especially the phosphatidylinositol and cyclic adenosine monophosphate (cAMP) second messenger systems. Extracellular signal-related kinase pathways may mediate lithium's antimanic effects [38]. Lithium also may modulate phosphatases that have been implicated in the cause of bipolar disease [39]. Lithium also modulates the precursor uptake, synthesis, storage, catabolism, and release of serotonin, interacts directly with serotonin receptors, and modulates serotonin-receptor interactions [40].

Cardiac Effects

Increase in myocardial lithium may lower intracellular potassium concentrations, causing T-wave flattening and ST-segment abnormalities [41, 42]. Sinus and arteriovenous node dysfunction, intraventricular conduction delays, and fatal bradycardias have also been reported [43, 44].

Thyroid Effects

Li^+ ion concentrates in the thyroid gland, achieving concentrations four to five times those occurring simultaneously in the plasma. Normally the thyroidal response to thyroid-stimulating hormone is mediated by cAMP. The formation and

the action of the latter may be inhibited by lithium, however. Additionally, in rodent models, lithium has been shown to reduce organification of iodine and colloid formation [45–47]. Lithium therapy is associated with an approximately sixfold risk of clinical hypothyroidism, compared with placebo, despite an increase in mean thyroid-stimulating hormone concentrations [48]. Parathyroid hormone and serum calcium concentrations are also increased, though generally not to clinically significant levels [48].

Renal Effects

Acute or chronic exposure to lithium can cause a loss in renal urine-concentrating ability. In 1970, the unresponsiveness of the kidney to antidiuretic hormone (ADH) was reported in patients being treated with lithium [49]. On average, renal concentrating ability is reduced by 15% of normal maximum (-158 mOsm/kg) in patients on chronic lithium therapy [48]. Normally, ADH acts by stimulating renal adenylyl cyclase to produce cAMP. Lithium inhibits this reaction [50]. ADH regulates the renal water channel (aquaporin), and lithium treatment causes a downregulation of this channel [46]. The end result of this loss of renal concentration ability is diabetes insipidus, characterized by excessive free water loss and resulting hypernatremia. Free water loss continues in the face of intravascular volume depletion until the fall in glomerular filtration leads to acute renal failure. Although the hypothalamus responds to the presence of hypernatremia and hypovolemia by increasing ADH excretion, the kidney cannot respond adequately to this homeostatic mechanism [51]. Because of its nonresponsiveness to ADH, this effect is called *nephrogenic diabetes insipidus* (NDI). Lithium also may cause an alkaline urine and renal tubular acidosis [4].

Clinical Presentation

Lithium intoxication is characterized primarily by peripheral neuromuscular signs and, in more severe cases, central nervous system (CNS)

dysfunction. Renal manifestations of lithium toxicity, such as NDI, may occur with or without CNS signs. Lithium may have adverse effects on the thyroid gland and cardiac conduction system therapeutically and during periods of toxicity. Acute lithium toxicity is often associated with gastrointestinal symptoms. A modification of the grading scheme for lithium intoxication, promulgated by Hansen and Amdisen [3, 15, 52], is presented in Table 1.

Lithium intoxication is classically divided into *acute*, *chronic*, or *acute-on-chronic* presentations [53].

By definition, a patient with *acute lithium poisoning* is lithium naive and takes an overdose. Patients with acute lithium poisoning begin the episode of illness with negligible lithium concentrations in the brain, heart, and kidneys. Therefore, particularly in the early hours of the poisoning event, they tend to have few signs and symptoms of toxicity despite serum lithium concentrations far in excess of the “therapeutic” range.

In contrast, a patient with *chronic lithium poisoning* is prescribed lithium therapeutically, and typically some event decreases renal lithium

elimination. In the classic analysis of 123 cases of lithium intoxication by Hansen and Amdisen [3], aside from the obvious acute overdose, intravascular volume depletion in association with negative water balance was found to be the major predisposing factor for lithium intoxication. Volume loss from decreased intake, excessive perspiration, gastrointestinal fluid loss, or diuretics can predispose to lithium toxicity [54–57]. Similarly, drugs that decrease renal glomerular blood flow, most notably angiotensin-converting enzyme inhibitors, may cause lithium toxicity. Although nonsteroidal anti-inflammatory drugs decrease glomerular filtration rate, their propensity to induce lithium toxicity seems to be minimal [10]. Lithium-induced NDI and polyuria [10] can contribute to a vicious cycle of intravascular volume depletion and worsening toxicity. Because thiazide diuretics selectively act to decrease sodium (and increase lithium) reabsorption in the proximal tubule, they are most prone to cause lithium toxicity [58]. Patients with chronic lithium poisoning typically present with CNS manifestations, and serum lithium concentrations may be within or near the “therapeutic” range.

Acute-on-chronic lithium poisoning occurs when a patient on chronic lithium therapy takes an acute overdose. Although these patients begin the episode of illness with some tissue lithium burden, clinically these patients present similarly to those with acute lithium poisoning.

Neurologic Effects

For reasons described earlier, there is overall a poor correlation between serum lithium concentration and clinical presentation. Patients with lithium intoxication present with a clinical picture predominantly characterized by tremor, lower extremity hyperreflexia, ankle clonus, motor hyperactivity, increased tone and rigidity, drowsiness, apathy, sluggishness, ataxia, fasciculations, and stupor, in approximately that order of decreasing frequency [3, 53].

Most patients with lithium toxicity have abnormal electroencephalograms (EEGs) [3, 59]. Some

Table 1 Grading system for lithium intoxication [3]

Grade	Features
0	Asymptomatic
1	Any of the following
	Nausea
	Vomiting
	Tremor
	Hyperreflexia
	Agitation
	Muscle weakness
	Ataxia
	Drowsiness
2	Any of the following
	Stupor
	Rigidity
	Hypotension
3	Any of the following
	Coma
	Seizures
	Myoclonia
	Cardiovascular instability

Data from Refs. [3, 26, 49]

authors have suggested that EEG changes correlate better with lithium toxicity than do serum concentrations [60]. This has not been studied systematically, and it is unclear whether EEG provides any useful information beyond that available from a bedside physical and neurologic exam. EEG changes are typically polymorphic, with rhythmic slowing of theta and delta waves of moderate-to-high voltage. These can be continuous or paroxysmal and diffuse or focal. Epileptiform changes may occur and can even mimic status epilepticus [60]. In the series by Hansen and Amdisen [3], 83% of patients had EEGs on admission, all of which were severely abnormal, mostly with 2–5 Hz spikes and sharp waves. All of these EEGs showed improvement over time as the lithium toxicity resolved, and most of them normalized.

Although in most patients lithium-induced neurotoxicity is transient, there have been many reports of permanent neurologic sequelae in patients with lithium intoxication [3, 10, 60–65]. This phenomenon is referred to as the “syndrome of irreversible lithium-effectuated neurotoxicity (SILENT)” [66]. Patients are typically described as having parkinsonian findings, including tremor, bradykinesia, slowed cognitive processing, and dementia. Interpretation of these reports is limited, however, by the frequent lack of baseline information and other possible confounding factors, such as neuroleptic drug use, preexisting diagnoses, alcoholism, or brain damage due to other factors. To date no large studies have reported long-term follow-up of patients with SILENT, and the prognosis for recovery is therefore unknown.

Renal Effects

Many lithium-induced renal abnormalities have been described with both therapeutic use and intoxication. Various reports have described decreases in creatinine clearance [67, 68], oliguria [4, 67, 68] or polyuria [4, 53, 65–69], renal tubular acidosis [4, 53, 65–69], decreased urinary concentrating ability [4, 54, 66–70], and nephrotic syndrome [4, 5, 68]. Acute renal failure after lithium

intoxication is unusual, occurring in 7% of patients in one series [53]. As previously noted, renal failure can be both a cause and consequence of lithium poisoning.

Diabetes insipidus and hypernatremia have been reported to occur in 20% of patients during therapeutic use or episodes of lithium intoxication [53, 70, 71]. Many more patients have polyuria, polydipsia, decreased urinary concentrating ability, and increased thirst [72]. This diabetes insipidus is not usually responsive to vasopressin and is nephrogenic in origin.

Thyroid Effects

Hypothyroidism, even to the point of myxedema, occasionally is related to lithium therapy [73, 74]. Goiter has been described, as thyroid-stimulating hormone production is increased. The incidence of hypothyroidism associated with lithium therapy has been reported to be 1–20% [74–76]. Risk factors for developing lithium-induced hypothyroidism include female gender, a family history of thyroid disease, and age older than 60 [76]. Because hypothyroidism and depression can appear clinically similar, it is possible for the former to be overlooked. Because of the inhibitory effect of lithium on the thyroid, hyperthyroidism can be suppressed by lithium therapy [77]. An illustrative case report described a patient with lithium toxicity and no prior diagnosis of hyperthyroidism who developed thyroid storm after hemodialysis [77].

Cardiac Effects

Many electrocardiogram changes have been associated with therapeutic lithium use and toxicity, including nonspecific ST-T-wave changes, bradycardia, conduction blocks, and junctional rhythms [46, 78]. The most common effects seen with therapeutic use are T-wave flattening or inversion and depressed ST segments in the lateral leads (Fig. 1) [46, 78].

Fig. 1 ECG of a 53-year-old woman with chronic lithium toxicity (level 2.4 mEq/L) and acute delirium. She presented with junctional bradycardia and underwent emergent hemodialysis on day 1 and had spontaneous

conversion to normal sinus rhythm on hospital day 4. Note the diffuse T-wave inversion (*Courtesy of J. Ward Donovan, MD, Pinnacle Health Toxicology Center, Harrisburg, PA*)

Diagnosis

The diagnosis of lithium toxicity usually is made on the basis of the clinical history, determination of serum or plasma lithium concentration, and clinical suspicion. In the absence of a history of lithium ingestion, patients who present with the various clinical features described in the preceding section, such as altered mental status, tremor, lower extremity hyperreflexia and ankle clonus, and diabetes insipidus, should be suspected of having lithium toxicity. If a patient has a history of psychiatric disorder or access to lithium in the environment, this should heighten the suspicion.

Lithium typically is assayed in the plasma using emission photometry, atomic absorption spectroscopy, or a Li^+ ion-specific electrode. In most instances, serum or plasma lithium concentrations are measured, and most clinical experience is with these analyses. Some authors have suggested that a better correlate of tissue lithium concentrations is provided by measurement of red blood cell lithium concentrations; however, there

is little clinical experience with the interpretation of these latter values. Inadvertant collection of blood samples in a tube containing lithium heparin anticoagulant (green top) can cause false elevation of serum lithium concentrations [79]. Because lithium is an unmeasured cation, lithium poisoning has been described to cause a narrow or even negative anion gap [80]. Because the normal anion gap is approximately 12 mmol/L and even cases of acute lithium poisoning rarely feature serum concentrations exceeding 5 mmol/L, this is probably a rare and insensitive finding.

The serum lithium concentration must be interpreted in the context of whether the patient may have had an acute overdose, has been on long-term lithium therapy, or both. Once the diagnosis of lithium poisoning has been confirmed, serial measurements of serum lithium concentrations will help guide management.

Renal failure can be both a cause and consequence of lithium poisoning, and renal function should be assessed in all cases of suspected lithium poisoning. Because of the risk of NDI, serum sodium should be measured, and patients should

be watched for polyuria. If polyuria is present, measurement of serum and urine electrolytes and serial serum sodium measurements are necessary to evaluate and safely manage NDI.

Given the propensity of lithium to induce hypothyroidism, measurements of free thyroxine and thyroid-stimulating hormone are appropriate.

Acute Toxicity

Patients with acute lithium toxicity generally presents with markedly elevated plasma or serum lithium concentrations and a relative paucity of clinical signs, particularly if presentation is early after overdose. This represents the phase during which lithium is primarily in the plasma and has not distributed yet into tissues. If plasma lithium concentration remains elevated for a prolonged time, however, it may distribute into various tissue compartments, and clinical manifestations may become evident thereafter. Because lithium exerts its neurologic effects while resident in the brain, and because distribution of lithium into and out of the brain is slow, the development and resolution of these clinical manifestations lag behind the initial rise and subsequent fall in plasma concentrations.

Chronic Toxicity

The diagnosis of chronic lithium toxicity can be much more challenging than the diagnosis of acute lithium overdose. These patients may have significant tissue lithium stores yet have modest plasma lithium concentrations [3, 53, 81]. Neurologic findings and NDI may persist even after serum and tissue lithium concentrations have fallen to low or undetectable levels.

Treatment

As with all poisonings, the treatment of lithium intoxication may require aggressive management of the patient's airway and ventilation and circulatory support, depending on clinical severity.

Patients who are lithium intoxicated may be hypermetabolic, may be diaphoretic, may have decreased fluid intake or frank emesis, and are likely to be intravascularly volume depleted. Because lithium clearance depends on glomerular filtration rate, fluid resuscitation to reestablish normal intravascular volume and restore normal urine flow is paramount. Because lithium clearance increases with sodium loading [29], resuscitation with isotonic saline to the point of normal intravascular volume clinically with attainment or maintenance of eunatremia may enhance lithium's renal clearance (grade III recommendation). Once this has been achieved, urine output should be closely monitored. If NDI develops, targeted fluid replacement with half-normal saline or even 5% dextrose in water (D5W) may be needed to replace free water losses and maintain eunatremia and euvolemia.

Patients who have severe lithium toxicity may have many secondary complications, including seizures, acute renal failure, severe rhabdomyolysis, and adult respiratory distress syndrome. These complications should be treated by standard supportive measures, with no specific treatment indicated as a result of their occurrence in the context of lithium toxicity.

Gastrointestinal Decontamination

Gastrointestinal decontamination is likely of limited benefit to patients with lithium poisoning, with the possible exception of patients with acute or acute-on-chronic lithium poisoning and impaired renal function.

Activated Charcoal

Lithium does not bind to activated charcoal, and activated charcoal administration has no established or theoretical role in the management of lithium poisoning [82].

Gastric Lavage/Whole-Bowel Irrigation

Gastric lavage has not been shown to alter the outcome or clinical course of patients who have overdosed on lithium and is unlikely to be beneficial. Although whole-bowel irrigation has been

shown to reduce lithium absorption in a randomized crossover study using healthy volunteers, this study used a dose of polyethylene glycol/electrolyte lavage solution (2 L/h for 5 h) that is difficult to safely achieve in clinical practice [83]. Although anecdotal reports suggest that whole-bowel irrigation may decrease absorption, there are no controlled data relating to the effect, if any, of whole-bowel irrigation on either outcome or clinical course of patients who have lithium toxicity. Because whole-bowel irrigation is relatively free of adverse effects, it is reasonable to employ this technique in patients who have successively increasing serum lithium concentrations or who have ingested large amounts of a delayed release preparation (grade III recommendation). Whole-bowel irrigation should only be done, however, in patients whose airways are protected naturally or by virtue of intubation and who have intact bowel function. It is unlikely that whole-bowel irrigation will be beneficial unless the polyethylene glycol solution is given rates that could only be achieved via a naso- or orogastric tube. Although there are no validated protocols for using whole-bowel irrigation, we recommend administration at a rate of at least one liter per hour in individuals greater than 6 years of age and 500 mls per hour if between 9 months and 6 years old. We do not recommend this technique for infants under 9 months.

Indications for ICU Admission in Lithium Poisoning

Significant manifestations of toxicity (e.g., altered mental status, rigidity, hyperreflexia)
Nephrogenic diabetes insipidus (NDI) requiring close monitoring of urine output and serum sodium
Cardiovascular instability
Significant toxicity in which extracorporeal removal (hemodialysis or continuous renal replacement therapy) is planned
Supratherapeutic and rising serum lithium concentrations, in settings in which frequent reassessment and decision-making cannot be achieved in a less intense setting

Sodium Polystyrene Sulfonate

The cation-exchange resin sodium polystyrene sulfonate (SPS, Kayexalate®) binds lithium in vitro [84, 85]. Many animal studies, reviewed in detail by Scharman [86], have shown that SPS administration can reduce measured serum lithium concentrations after either single or multiple doses of the latter. This reduction has been shown to occur when SPS is given after a significant delay following oral administration [87] and even when the lithium was administered intravenously [88]. These two studies show that SPS in the gastrointestinal tract has the capability of decreasing the absorption of lithium and enhancing its clearance. These animal studies used larger doses of SPS (2.5–5 g/kg) than typically are used to treat hyperkalemia in humans (0.5 to g/kg) [86, 89]. It is unlikely that these larger doses can be administered without a significant risk of causing hypokalemia.

Two human volunteer studies showed that doses of SPS of less than 1 g/kg can reduce the absorption of small amounts of lithium [81, 82]. A case report of a patient with lithium overdose described treatment with 150 g of SPS over a 24-h period without significant adverse effects. The authors of this report cited the patient's elimination half-life of lithium of 12 h as evidence of SPS's efficacy [83].

The optimal dose of SPS is unknown. It seems that a single dose of 1 g/kg may reduce lithium concentrations without significantly affecting either serum sodium or potassium concentrations [82] (grade III recommendation). Whether this dosing would result in meaningful clinical improvement and the safety and utility of repeated SPS dosing is unclear. If SPS is administered, cardiac monitoring, frequent measurement of serum sodium and potassium, and replacement of potassium are mandatory. Based on the above, we do not recommend the use of SPS in the routine management of lithium intoxication. In very large overdoses, or in patients with very high serum lithium concentrations in whom hemodialysis cannot be performed, SPS maybe a useful adjunctive therapy. There are no data indicating that SPS treatment alters the outcome of lithium-toxic patients.

Enhancement of Elimination

A fundamental goal in the treatment of lithium toxicity is the enhancement of its elimination. Generally, studies aimed at evaluating the utility of this approach have focused on clearance of lithium from the vascular compartment. This clearance usually is accomplished easily and quickly, particularly in patients with normal renal function. Physiologically, it is most important, however, to remove the lithium from target tissue compartments, particularly the brain. Because this removal cannot be done directly, the indirect approach of clearing the plasma of lithium and creating a concentration gradient that leads to diffusion of lithium from tissues to plasma is employed.

Renal elimination of lithium effectively constitutes the exclusive means by which it is naturally cleared from the body. Because renal lithium clearance is a direct function of glomerular filtration rate, it is important to reestablish and then maintain normal intravascular volume and renal perfusion. Normal saline treatment has been shown to enhance lithium and creatinine clearance in a group of lithium-intoxicated patients [3, 53, 90] (grade II-3 recommendation). Hospitalized psychiatric patients with bipolar disorder who are opposed to their lithium therapy have been known to reduce their lithium concentrations by consumption of large amounts of table salt. Whether normal saline is efficacious because of the competitive effect of the sodium ion on proximal tubular cation uptake or simply by virtue of its utility in reconstituting glomerular filtration is unknown. As noted earlier, overzealous treatment with normal saline can result in hypernatremia in patients with clinical or subclinical NDI. There does not seem to be any role for diuretic administration, including osmotic or loop diuretics [3, 29, 53]. Thiazide diuretic administration may increase serum lithium concentrations and may precipitate toxicity [91–94].

Extracorporeal Techniques

Hemodialysis

Lithium is well cleared by hemodialysis, with reported clearances of 63–170 mL/min [3, 17,

34, 95]; this compares favorably with an endogenous clearance of 13–56 mL/min [95]. Similarly, half-lives of lithium range from 2.3 to 12.9 h on hemodialysis [15, 17, 95]. Most of these studies were done with older-generation dialysis membranes. High-flux hemodialysis membranes are likely to enhance lithium elimination markedly [96–98]. In one report, lithium half-life during hemodialysis with a high-flux system was 1.4–1.9 h [96]. It is possible that acetate hemodialysis is more efficient than hemodialysis performed with bicarbonate-containing dialysate for the removal of intracellular lithium [97]. It has been hypothesized that acetate, being a weak acid, moves into the cell along with protons via the Na^+/H^+ transporter, with resultant net lithium efflux rather than sodium efflux [97].

Continuous Hemodialysis, Hemofiltration, Hemodiafiltration, and Related Techniques

Clearances reported with continuous extracorporeal removal techniques tend to be less than clearances achievable with hemodialysis. Continuous techniques have the advantage of being simpler than hemodialysis, however, and often can be used when the latter is unavailable or the patient is too unstable hemodynamically to undergo effective hemodialysis. Lithium clearances with continuous arterial-venous hemodiafiltration have been reported to be 20–56 mL/min [99, 100]. Clearances with continuous venovenous hemofiltration and/or hemodiafiltration have been reported to range from 27 to 83 mL/min [100–103]. Clearances with continuous venovenous hemodialysis have been reported to be 15–23 mL/min [100, 104]. None of the continuous techniques provide clearances that approach those attainable with hemodialysis. In a patient who cannot tolerate hemodialysis because of hemodynamic instability, however, or if these facilities are unavailable, continuous arterial-venous hemodiafiltration or continuous venovenous hemodiafiltration seems to be preferable to continuous venovenous hemodialysis.

Peritoneal Dialysis

Peritoneal dialysis has been reported anecdotally for the enhancement of lithium clearance

[3, 105, 106]. It is typically done with 2 L/h fluid volume exchanges; however, the clearances reported were only 9–15 mL/min. As a result, peritoneal dialysis has no recognized role in the management of lithium poisoning.

Indications for Extracorporeal Removal

Two recent systematic reviews have examined the question of which patients, if any, benefit from extracorporeal lithium removal. The authors of a Cochrane Collaboration review concluded that, “although the use of hemodialysis to enhance the elimination of lithium in lithium poisoning appears logical, there is no evidence from randomized controlled trials to support nor refute the use of hemodialysis in the management of patients with lithium poisoning” [107].

In contrast, a systematic review conducted by the Extracorporeal Treatments in Poisoning (EXTRIP) workgroup recommended the use of hemodialysis for lithium-poisoned patients with specific clinical features [108]. Acknowledging the very low quality of evidence, the EXTRIP authors based their recommendations primarily on pharmacokinetic considerations using a structured consensus-building process.

EXTRIP Workgroup Recommended Indications for Extracorporeal Drug Removal in Lithium Poisoning

Indications for Extracorporeal Drug Removal (ECDR)

Severe lithium poisoning (decreased level of consciousness, confusion, seizures, or life-threatening dysrhythmias)

Serum lithium concentrations >5.0 mEq/L

Serum lithium concentrations >4.0 mEq/L with impaired kidney function

Expected time to obtain a serum lithium concentration <1.0 mEq/L with optimal management is >36 h

Technique for ECDR:

Intermittent hemodialysis is the preferred modality

Continuous renal replacement therapy is an acceptable alternative if intermittent hemodialysis is not available

Criteria for Cessation of ECDR

Serum or plasma lithium concentrations remain <1.0 mEq/L after post-dialysis redistribution.

Clinical improvement is evident.

If serum lithium concentrations are not available, after a minimum of 6 h of ECDR.

Source: [108].

Similarly, the authors of most previously published case series, review articles, and textbook chapters generally recommend hemodialysis therapy for patients with lithium poisoning, but the specific indications for extracorporeal therapy are inconsistent. Like the EXTRIP review, most authors base their recommendations on serum lithium concentration, renal function, and clinical status [3, 8, 26, 90, 95, 109–114]. One indication that is consistently supported is compromised renal function because this would impair the elimination of lithium in the absence of an extracorporeal removal intervention. In addition, if hemodialysis does confer any improvement in outcome, it is likely that patients with Hansen and Amdisen grade III toxicity (see Table 1) would be the population most likely to benefit, while grade 0 patients with intact renal function are unlikely to achieve any improvement in prognosis. For patients with grade I or grade II toxicity and intact renal function, most authors recommend rehydration, serial clinical examinations, and serial lithium concentration measurements, with hemodialysis reserved for those patients with worsening clinical toxicity and rising or minimally decreasing serum lithium concentrations. A recent study showed substantial variation in recommended treatment when standardized lithium poisoning cases were presented to a group of medical toxicologists [115].

As noted by both the Cochrane and EXTRIP authors, hemodialysis has not been shown, under any circumstances, to alter patient outcome after lithium intoxication. A study conducted in a poison control center examined outcomes in 205 patients with lithium poisoning for whom hemodialysis was recommended over a 1-year

period [15]. Dialysis was actually performed in nine cases, and there was no apparent difference in outcomes between dialyzed and nondialyzed patients. However, this study is highly susceptible to confounding by indication and may have been underpowered to detect an important treatment difference. In essentially all published case series, the majority of acutely lithium-poisoned patients never develop SILENT, and most chronic lithium intoxication patients who develop SILENT have the condition present on presentation [3, 44, 107, 116]. Furthermore, one systematic review noted a greater incidence of persistent neurologic sequelae and deterioration during hospitalization in patients managed with hemodialysis than those who were not dialyzed [117]. Because this study could not control for confounding by indication, it is unclear whether hemodialysis is harmful to some patients or if patients with more serious illness received the treatment.

A rebound in plasma lithium concentration is seen frequently after the termination of hemodialysis [17, 95]. This rebound undoubtedly represents diffusion of lithium ions from peripheral tissues to the plasma and serum. Steady decreases on CSF lithium concentrations despite a posthemodialysis rebound in serum lithium concentration has been clearly demonstrated in a human case report [36]. Serum lithium concentrations may also increase due to continued gastrointestinal absorption. Although most authors recommend repeat hemodialysis sessions until a post-rebound concentration (measured 6 or more hours after the last hemodialysis session) is less than 1 mmol/L, this appears to be an arbitrary recommendation without basis in clinical observation [108]. Alternately, implementation of continuous veno-venous hemodiafiltration following acute hemodialysis has been shown to attenuate the rebound in serum lithium concentrations [118].

Other Therapies

Because theophylline, like aminophylline (the intravenous form of theophylline), has been reported to increase renal clearance, these agents have been investigated as potential adjunctive treatments for lithium toxicity [29]. This potential

has been studied only in volunteers, however, in whom the effect of theophylline on lithium clearance has been highly variable.

A single uncontrolled case report describes the attempt to enhance glomerular filtration with low dose of dopamine (2 µg/kg/min) to enhance lithium excretion [119].

As noted earlier, there are data in a rodent model of lithium toxicity suggesting that SPS may be effective in enhancing the clearance of already absorbed Li^+ ion. As described above, whether there is any clinical utility to this approach is unknown.

Treatment of Nephrogenic Diabetes Insipidus

NDI may be an overt clinical consequence of lithium therapy or may be subclinical and only manifested with the institution of normal saline therapy in an attempt to treat lithium toxicity. The fundamental deficit in NDI is loss of free water, as the kidney continues to produce a large volume of dilute urine despite high serum sodium levels and osmolality. Treatment, therefore, primarily should involve administration of intravenous hypotonic fluids, such as half-normal saline or 5% dextrose in water or enteral administration of water. Antidiuretic hormone therapy is typically ineffective. The reconstitution of intracellular and extracellular fluid volume using these fluids should be done cautiously. Although the fluid deficits can be large, the administration of half-normal saline too rapidly may result in relative overexpansion of the extracellular compartment. The administration of 5% dextrose too rapidly may exacerbate hyperglycemia in a patient with glucose intolerance and on the basis of concomitant osmotic diuresis may aggravate the fluid volume loss. In either instance, we recommend that the fluid volume deficit should be corrected gradually, with frequent monitoring of serum sodium levels.

Criteria for ICU Discharge in Lithium Poisoning

Falling or nondetectable serum lithium concentrations

Resolving clinical signs of toxicity

The goal of therapy is to gradually correct fluid volume deficits comprising the sum of the intracellular and extracellular volume losses. Normal intracellular fluid (ICF) volume is approximately 0.4 L/kg. A reliable estimate of the patient's actual ICF may be obtained using the following equation:

$$\text{ICF} = \frac{(\text{normal ICF} \times [2 \times \text{normal serum Na}^+]) \times \text{weight}}{2 \times \text{measured Na}^+}$$

In this equation, normal ICF is 0.4 L/kg, and normal serum sodium is 140 mmol/L. In a 70-kg patient, the normal ICF would be 0.4 L/kg \times 70 kg or 28 L. If with lithium-induced NDI, the serum Na^+ is 150 mmol/L; the actual ICF would be approximately 26 L, representing a 2-L ICF deficit. The calculation of the extracellular fluid (ECF) volume cannot be done simply based on the measured serum Na^+ but rather must be estimated on clinical grounds. The normal ECF is approximately 0.2 L/kg or 14 L/70 kg. It reasonably can be assumed that hyponatremic patients with NDI and relatively normal physical examinations have an approximately 10% decrease in ECF, although if signs of volume depletion are present, this can be 20%. If ECF volume decreases to 30% of normal, the patient is in frank circulatory shock. The total fluid volume deficit in need of replacement is the sum of the calculated ICF and estimated ECF deficits. An alternative, and in some cases simpler, approach to estimating the total free water deficit (FWD) is to use the following formula and make empirical adjustments in replacement therapy:

$$\text{FWD} = \frac{(\text{measured serum } [\text{Na}^+] - 140) \times 0.66 \text{ wt (kg)}}{140}$$

Adjunctive therapy with hydrochlorthiazide and/or amiloride may reduce the duration and severity of lithium-induced nephrogenic diabetes insipidus. In this setting, HCTZ has a paradoxical antidiuretic effect by increasing aquaporin-2 receptor abundance and affects the expression of major renal sodium transporters, among other mechanisms [120–122]. However, as thiazide diuretic administration may reduce lithium

elimination, this approach is best avoided in patients with measurable serum lithium concentrations [58, 91–94]. Similarly, amiloride has been reported to significantly reduce urine volume and increase urine osmolality in patients with lithium-induced NDI [123].

Special Populations

Pregnant Patients

Concern for the teratogenic potential of lithium has arisen from the demonstration, in several animal experiments, of adverse fetal outcomes occurring in treated pregnant dams [124, 125]. These abnormalities occurred, however, only when animals were given overt maternally toxic amounts of lithium, were markedly dissimilar in various species, and did not occur in lithium-treated primates [126].

In response to the possible teratogenic risk of lithium, a registry of treated patients was initiated in Denmark in 1969 [127]. Similar registries were formed in other countries, leading ultimately to the International Register of Lithium Babies [124, 127, 128]. Based on the results of these registries, concern about potential adverse effects, particularly Ebstein's anomaly, surfaced. These registry data are uncontrolled, however, and prone to ascertainment bias. In contrast, there have been eight epidemiologic studies of offspring outcome among women treated with lithium during pregnancy: two cohort trials broadly dealing with teratogenicity and six case-control studies [124]. Collectively the data from these studies indicate that the initial concern for fetal risk raised by registry data was not verified. Risk has not been ruled out completely, however, and it may be prudent to avoid lithium therapy, particularly during the first trimester of pregnancy, if the goals of treatment can be achieved by other means. In patients in whom lithium treatment is strongly indicated, it has been suggested that pregnancy be monitored by fetal echocardiography and ultrasound evaluation during the mid-second trimester [124]. Consistent with the demonstration that lithium crosses the placenta, a case has been

published suggesting transient neonatal lithium toxicity after birth from a lithium-toxic mother [129].

Because of the high glomerular filtration rate in pregnancy, renal lithium clearance is high. Given the rapid postpartum decline and normalization of glomerular filtration rate, it is important to reduce the maternal lithium dose and monitor plasma concentrations closely after parturition.

Although some lithium is excreted in breast milk, breastfeeding infants of treated mothers tend to have low-circulating lithium concentrations [125, 130]. As would be expected with older individuals, however, should the infant become volume depleted, serum lithium concentrations might rise.

Other Patients

Because lithium clearance depends completely on renal excretion, patients with decreased renal function are at particular risk for lithium toxicity. The presence of renal insufficiency should be considered at least a relative contraindication for treatment. Even in the absence of frank overt elevations in serum creatinine, normal decline in renal function with age suggests that the elderly are particularly vulnerable to lithium toxicity.

Common Errors in Lithium Poisoning

Thinking that diuresis beyond adequate urine production enhances lithium excretion

Failure to recognize significant lithium toxicity in the presence of normal or minimally elevated plasma concentrations

Key Points in Lithium Poisoning

1. Any factor that causes a decrease in lithium's renal clearance may predispose to toxicity.
2. Lithium toxicity is caused by its concentration in tissues (e.g., brain, kidney, thyroid),

and plasma lithium concentrations may not reflect accurately the degree of intoxication.

3. Lithium is cleared renally. Its clearance may be enhanced further by hemodialysis.
4. Nephrogenic diabetes insipidus is a potential complication of its therapeutic use and toxic exposure.

Monoamine oxidase (MAO) inhibitors were serendipitously discovered in the 1950s when tuberculosis patients in Swiss sanitariums treated with isoniazid were noted to experience mood-elevating effects. Iproniazid, another antitubercular hydrazine derivative, was discovered to inhibit monoamine oxidase and had even greater psychostimulatory effects than isoniazid [1]. This led to its use as an antidepressant and paved the way for the development of the first effective agents in the treatment of major depression, the nonselective irreversible MAO inhibitors. MAO inhibitors have been in clinical use since the 1960s although their use has been supplanted by newer antidepressants, such as selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) that have fewer serious adverse effects and are less hazardous in overdose. Their continued decline in use is confirmed by data from the American Association of Poison Control Centers Toxic Exposure Surveillance System which recorded 3,261 total exposures to MAO inhibitors with 12 fatalities from 2001 to 2013 [2–13]. This is compared to 6,076 total exposures and 58 fatalities for the period from 1989 to 2000 [14–24].

Despite their waning popularity, MAO inhibitors are still listed as third- and fourth-line therapy for treatment-refractory or atypical depression [25, 26]. They also have produced positive responses and are used in other conditions, such as social phobia disorders, panic disorders, posttraumatic stress syndrome, obsessive-compulsive disorder,

Table 1 Monoamine oxidase inhibitors

Generic name	Trade name in United States ^a	Available in United States	Inhibits MAO-A	Inhibits MAO-B	Irreversible	Reversible
Brofaromine			X			X
Cimoxatone			X			X
Isocarboxazid	Marplan	X	X	X	X	
Moclobemide	Aurorix, Manerix		X			X
Phenelzine	Nardil	X	X	X	X	
Rasagiline	Azilect	X		X	X	
Selegiline	Eldepryl, Emsam	X		X	X	
Toloxatone			X			X
Tranylcypromine	Parnate	X	X	X	X	

^aUnited State tradenames are given as examples. Although the genric names of these agents are universal, their trade names differ between countries

bulimia, and narcolepsy [27]. As a result, populations at risk for suicidal ingestions or intentional overdose may continue to have accessibility to MAO inhibitors. Their complex pharmacology coupled with unfavorable adverse effect profile and the potential for food (e.g., tyramine reaction) and drug (e.g., serotonin syndrome) interactions, along with a low therapeutic index and potential for fatality when taken in overdose, means clinicians must remain knowledgeable and prepared to manage severe manifestations of MAO inhibitor toxicity and the anticipated complications.

This chapter focuses on the traditional nonselective and irreversible MAO inhibitors due to their increased likelihood to produce severe toxicity. However, major advances in developing less toxic MAO inhibitors, which are reversible and selective in their MAO activity (Table 1), have occurred. These agents will be discussed briefly but their toxicity seems to be less severe than that of irreversible MAO inhibitors and many are not available in the United States. The MAO inhibitors currently available in the United States including phenelzine (Nardil), tranylcypromine (Parnate), isocarboxazid (Marplan), selegiline (Eldepryl, Emsam), rasagiline (Azilect). Selegiline (Eldepryl), and rasagiline (Azilect) are selective MAO B inhibitors that are used as an adjunct in the treatment of Parkinson's disease [28]. At higher doses, selegiline resembles the activity of traditional MAO inhibitor antidepressants. It is currently available in a transdermal

formulation and indicated for use in the treatment of depression [28]. In the United States, MAO inhibitors are not approved for use in children younger than 16 years of age and use should be avoided during pregnancy.

Monoamine Oxidase Inhibitors Available in the United States

Isocarboxazid (Marplan) – used as an antidepressant

Phenelzine (Nardil) – used as an antidepressant

Rasagiline (Azilect) – used to treat Parkinson's disease

Selegiline (Eldepryl, Emsam) – used as an antidepressant and to treat Parkinson's disease

Tranylcypromine (Parnate) – used as an antidepressant

Some drugs have been discovered to have MAO inhibitor activity as an unrelated pharmacological action. Examples include methylene blue, the antidote for methemoglobinemia; linezolid and tedizolid, oxazolidinone antibiotics; procarbazine (Matulane), a chemotherapeutic agent; and zonisamide (Zonegran), an anticonvulsant that has selective MAO B inhibition [29]. Agents that are known to have MAO inhibitor activity but have been withdrawn from the market in the United Sates, and several other countries, include furazolidone (Furoxone), a synthetic nitrofuran with antimicrobial and

antiprotozoan activity, and pargyline (Eutonyl), whose use was discontinued in the 1990s. The latter was an antihypertensive agent whose primary mechanism of action was MAO inhibition. Clorgyline is an irreversible MAO A inhibitor withdrawn from the market in many countries but still is used for experimental purposes.

Herbal products, such as the popular over-the-counter treatment for depression St. John's wort (*Hypericum perforatum*), has been reported to have slight MAO inhibitor activity [30]. However, St. John's wort functions more like a nonselective neurotransmitter reuptake inhibitor than like an MAO inhibitor [30]. Most patients taking St. John's wort do not consider it a drug and often omit herbal products when being asked about their medications. Harmaline alkaloids found in the plant *Peganum harmala* inhibit MAO activity. There are reports of harmaline being abused with the drugs of abuse 5-methoxy-*N,N*-diisopropyltryptamine and 5-methoxy-*N,N*-dimethyltryptamine to enhance their hallucinogenic effects [31–35].

Biochemistry, Pathophysiology, and Clinical Pharmacology

MAO is an intracellular enzyme bound to the outer mitochondrial membrane. It can be found in most human cells with the exception of erythrocytes, which lack mitochondria. MAO removes amine groups from endogenous and exogenous biogenic amines. This oxidative deamination process is the primary mechanism by which endogenous biogenic amines, such as norepinephrine, dopamine, and 5-hydroxytryptamine (serotonin) [36], become inactivated. An equally important function of MAO is the reduction in systemic bioavailability of absorbed dietary biogenic amines, such as tyramine, via hepatic and intestinal metabolism. Inhibition of MAO leads to the accumulation of neurotransmitters in central and peripheral presynaptic nerve terminals and allows for increased systemic availability of dietary amines [36]. MAO does not metabolize circulating catecholamines, whether they are secreted endogenously (e.g., adrenal gland, sympathetic

nerve terminals) or administered intravenously (e.g., epinephrine). This metabolism is accomplished by catechol *O*-methyltransferase, an extraneuronally located enzyme that is not affected by MAO inhibitors [36].

MAO exists as two separate isoenzymes, designated MAO-A and MAO-B. Evidence of the separate isoenzymes was initially provided by their protein chemistry. Now the two genes encoding human MAO A and MAO B have been identified [37]. Despite nearly 70% structural similarity, subtle differences in their binding cavities result in very different substrate and inhibitor specificities [37]. Each isoenzyme has a unique affinity profile for different neurotransmitters, dietary amines, and MAO inhibitors [31, 32, 36]. These substrate preferences are dose dependent and become less relevant at higher substrate concentrations or MAO inhibitor doses. Norepinephrine and serotonin are metabolized primarily by MAO-A, whereas MAO-A and MAO-B have equal ability to metabolize dopamine and tyramine [31, 32, 36]. MAO-B is the exclusive isoenzyme found in serotonergic neurons [30]. This paradox may be explained by simple conservation of energy, in which the MAO-B isoenzyme has a lower affinity for 5-HT and allows for more 5-HT to become recycled. It also allows for increased metabolism of nonserotonin bioamines, keeping the neuron free of false neurotransmitters.

The human brain contains more MAO-B than MAO-A, with MAO-B predominance increasing with advancing age and in some neurodegenerative diseases. Dopaminergic neurons appear to lack MAO-B activity and have limited MAO-A activity [31, 36]. Significant MAO-B activity has been detected in surrounding astrocytes and glial cells. Dopamine inactivation may depend on astrocyte and glial cell metabolism [31, 36]. MAO-A constitutes approximately 75% of the MAO activity in the intestine, whereas approximately equal proportions of both isoenzymes are found in the liver. When only one isoenzyme is inhibited, such as in the presence of moclobemide, which selectively inhibits MAO-A, this dual representation of both isoenzymes in the intestines and liver affords greater protection against the hypertensive reaction to

Fig. 1 Chemical structures of monoamine oxidase inhibitors and pertinent neurotransmitters

tyramine-containing foods. Similarities in chemical structure between MAO inhibitors and endogenous amines, such as norepinephrine, serotonin, and dopamine, make them eligible as potential substrates for MAO and cause inhibition of amine metabolism (Fig. 1) [32]. The antidepressant activity of phenelzine, tranylcypromine, and isocarboxazid is attributed to their ability to increase norepinephrine and serotonin neurotransmission by increasing presynaptic concentrations of serotonin and norepinephrine [31]. The actual mechanism by which they exert their therapeutic action is unproven but more likely is related to delayed postsynaptic receptor modifications (e.g., downregulation). Other potential mechanisms of action include indirect release of neurotransmitters and inhibition of neurotransmitter reuptake. MAO inhibitors also inhibit other enzyme systems (e.g., pyridoxal phosphokinase, diamine oxidase), but this is of uncertain clinical significance.

Phenelzine, like isoniazid, can cause pyridoxal phosphate deficiency which may contribute to its neurotoxicity [38]. Selegiline has limited effects on norepinephrine and serotonin metabolism at

therapeutic doses (typically 10 mg/day). At doses greater than 30 mg/day, however, selegiline is capable of increasing presynaptic norepinephrine and serotonin concentrations and has the potential to produce similar drug-related toxicity to that of nonselective MAO inhibitors, such as phenelzine and tranylcypromine [28]. Selegiline's therapeutic benefit in Parkinson's disease is thought to be related to increasing striatal dopamine neurotransmission and protection against neuronal damage from oxidative stress [28]. Oxygen is another substrate for the MAO enzymes, which results in the generation of H_2O_2 at the outer surface of the mitochondrial membrane. This is thought to increase oxidative stress and be deleterious to the cell, which is why MAO inhibitors are being evaluated and pursued as potential neuroprotective agents. However, further research is needed to fully understand the role of H_2O_2 as a cell signal and disease-modifying target [37].

All of the currently available MAO inhibitors in the United States are irreversible and nonselective (MAO-A, MAO-B) in their enzyme

inhibition with the exception of selegiline and rasagiline. The latter are irreversible MAO-B selective inhibitors. Irreversible MAO inhibitors form covalent bonds with MAO enzymes rendering them permanently inactive [31]. When an irreversible MAO inhibitor has been discontinued, it takes approximately 2 weeks before new enzyme synthesis returns MAO activity to 50% of normal [30, 31]. This is the basis for the recommendation of waiting 2 weeks after the discontinuation of an irreversible MAO inhibitor before starting any new antidepressant or proserotonergic agent. MAO inhibitors do not affect enzyme production. Reversible MAO inhibitors (RIMAs) do not form irreversible covalent bonds with MAO. New enzyme synthesis is not necessary to restore MAO, and MAO activity gradually returns to normal over a period of hours as the drug-enzyme complex spontaneously dissociates [39]. Examples of reversible MAO inhibitors include moclobemide, toloxatone, brofaromine, and cimoxatone which are only available internationally.

Pharmacokinetics

Although MAO inhibitors have been used since the 1960s, there is a scarcity of information regarding their pharmacokinetics [36, 39]. In general, they are absorbed rapidly and completely from the gastrointestinal tract but undergo significant first-pass hepatic metabolism, limiting their bioavailability. Their dependence on hepatic metabolism predisposes MAO inhibitors to potential drug interactions with other drugs requiring hepatic oxidation. Peak drug levels usually occur 1–4 h after ingestion. Their volumes of distribution are relatively small (1–3 L/kg) compared with other antidepressants. Their degree of plasma protein binding is unknown, and their elimination half-life averages 2–3 h [40].

Selegiline has many active metabolites, such as desmethylselegiline, *l*-methamphetamine, and *l*-amphetamine. Phenelzine metabolism results in multiple active metabolites, such as B-phenylethylamine, which also serves as a substrate for MAO-B [40]. Tranylcypromine

metabolism has not been fully elucidated. It was suspected to result in generation of amphetamine as a metabolite, but this is not supported by recent literature [41–43].

Clinical toxicity usually is delayed until well after most of the MAO inhibitor already has been metabolized. Blood MAO inhibitor concentrations do not correlate with clinical toxicity. The pharmacokinetic profile of most MAO inhibitors suggests that attempts at extracorporeal removal (e.g., hemodialysis) or administering repeat-dose activated charcoal would be unsuccessful in significantly reducing MAO inhibitor plasma concentrations.

Biphasic postmortem changes have been reported with tranylcypromine and moclobemide in fatal overdose cases [44, 45]. Initially, MAO inhibitor blood levels increase in a similar, but less dramatic, fashion as other antidepressants. After 24 h, drug concentrations show a rapid decline, however, suggesting bacterial degradation.

Pharmacokinetics of Nonselective Irreversible Monoamine Oxidase Inhibitors

Volume of distribution: 1–3 L/kg

Absorption rate: rapidly absorbed in 1–2 h

Bioavailability: 50%

Peak levels: 2–4 h after ingestion

Protein binding: 50%

Metabolism: hepatic metabolism (P-450 system and acetylation)

Plasma half-life: 2–4 h

Active metabolites: no significant active metabolites

Clinical Presentation of Acute Overdose

There are two significant concerns regarding acute MAO inhibitor overdose. First, the lethal dose in relation to the therapeutic dose is smaller than with other antidepressants. Second, the clinical manifestations of toxicity typically are delayed well beyond the usual observation period of other antidepressants [46, 47]. These two

characteristics distinguish MAO inhibitors from the other antidepressants, which have a much higher therapeutic index and usually develop toxicity within 6 h after ingestion.

The usual therapeutic dose for most MAO inhibitors ranges from 0.25 to 1.0 mg/kg. Mild-to-moderate toxicity typically is seen with ingestions of less than 2 mg/kg. Severe toxicity often results from ingestions of 2–3 mg/kg. The potentially lethal dose of irreversible MAO inhibitors is reported to be 4–6 mg/kg [46]. Deaths have been reported in adults with 170 mg of tranylcypromine and 375 mg of phenelzine. Selegiline overdoses can produce similar toxicity as the traditional MAO inhibitor antidepressants as selective MAO inhibition is lost when therapeutic dosing is exceeded. The average therapeutic dose of tranylcypromine is 20–40 mg/day, with a maximum daily dose of 60 mg/day. Phenelzine's therapeutic dose is 45–75 mg/day, with a maximum of 90 mg/day. Isocarboxazid has a therapeutic dose range of 10–30 mg/day. Sheenan et al. reported dosing equivalents as 45 mg of phenelzine equal to 20 mg of tranylcypromine equal to 40 mg of isocarboxazid [48].

An important clinical aspect of MAO inhibitor overdoses is that symptoms characteristically are delayed 6–12 h after ingestion but can be delayed 24 h [46, 47]. The delayed onset of toxicity is believed to be secondary to the gradual accumulation of norepinephrine and serotonin in the brain and peripheral sympathetic neurons which leads to excessive sympathetic receptor stimulation resulting in a hyperadrenergic state. Patients on long-term MAO inhibitor therapy may show earlier signs of toxicity owing to preexisting enzyme inhibition. In severe cases, the hyperadrenergic state can be followed rapidly by hypotension and central nervous system depression, a sympatholytic-like stage thought to reflect catecholamine depletion [46]. Toxicity usually persists 1–4 days after ingestion [46].

The signs and symptoms of MAO inhibitor toxicity are often nonspecific. Even in its most severe form, it can resemble numerous other conditions (see discussion of differential diagnosis

later). Information regarding MAO inhibitor overdoses primarily comes from limited case series [40, 49, 50] and isolated case reports [42, 51–57]. These reports have tremendous variation in presentation, treatment, and outcome. There is no “typical” presentation to MAO inhibitor toxicity, and there is not an orderly progression of symptoms. After an initial latent period, the rapid development of life-threatening symptoms in all patients with MAO inhibitor overdose should be anticipated. The initial symptoms of MAO inhibitor overdose include headache, agitation, irritability, tremor, nausea, and palpitations. The earliest signs of MAO inhibitor toxicity include sinus tachycardia, hyperreflexia, drowsiness, hyperactivity, mydriasis, fasciculations, hyperventilation, nystagmus, and generalized flushing [46].

In cases of moderate toxicity, opisthotonos, muscle rigidity, diaphoresis, hypertension, chest pain, diarrhea, hallucinations, combativeness, confusion, marked hyperthermia, and trismus may become evident [46]. A peculiar ocular finding has been observed with some cases of MAO inhibitor toxicity and is described as “Ping-Pong” gaze, in which the eyes move conjugately from one extreme lateral position to the other in a rhythmic fashion. The movement is smooth and without pause in cycles lasting 3–4 s [52, 57]. The mechanism of this gaze disorder is unknown. In all reported cases, it resolved gradually with patient improvement.

Severe toxicity is manifest by bradycardia, cardiac arrest, hypoxia, hypotension, papilledema, seizures, coma, and worsening hyperthermia. Hypotension is an ominous finding that commonly remains resistant to therapeutic attempts at correction [46, 52]. Fetal demise, cerebral edema, pulmonary edema, and intracranial hemorrhage all have been reported in association with MAO inhibitor overdoses [46, 52]. The most common electrocardiographic abnormality seen in MAO inhibitor toxicity is sinus tachycardia, but T-wave abnormalities also are common [46]. Deaths usually are secondary to multiple organ failure.

Overall, the newer reversible and selective MAO inhibitors seem to be less toxic in overdose than traditional MAO inhibitors. Most of these cases of newer MAO inhibitor overdose involve moclobemide [58–60], although one large case series involved toloxatone [61]. The toxicity of both of these antidepressants is similar in overdose and probably can be generalized to other selective and reversible MAO inhibitors. Most adult patients with ingestions of less than 2,000 mg are expected to remain asymptomatic or develop only minimal symptoms after a single drug overdose [62]. However, toxicity can become severe, when combined with other antidepressants or in large overdoses. Cases of severe serotonin syndrome and death following combination of moclobemide with either SSRIs or SNRIs have been described [62–65]. And death following intentional overdose of moclobemide has been reported [66]. The clinical manifestations of toxicity are similar to those described previously with irreversible agents and can be just as severe, although, the toxicity from reversible MAO inhibitors resolves sooner than with the irreversible agents, and the mortality rate is believed to be less.

MAO inhibitors can produce hypertension by several mechanisms. It may result from spontaneous hypertensive crisis, tyramine reactions

(see later), drug interactions, serotonin syndrome, or high-dose toxicity. Determining the cause of the hypertension depends largely on obtaining an accurate history of the preceding events. Spontaneous hypertensive crisis is a rare condition usually occurring in relation to recent MAO inhibitor dosing [67]. Hypertension can result from exposure to indirect-acting sympathomimetics commonly found in over-the-counter cold and sinus medications [68]. Hypertension may be a constellation of serotonin syndrome which most commonly occurs shortly after exposure to other serotonergic agents and can be severe [69]. The clinical presentation of the serotonin syndrome is discussed (see ► Chap. 24, “Serotonin Syndrome”).

Tyramine Reaction

Tyramine is a dietary amine that normally is metabolized by intestinal and hepatic MAO enzymes (Fig. 2), limiting its bioavailability. Nonselective MAO inhibitors interfere with this process, allowing for a greater amount of tyramine to reach the systemic circulation. Tranylcypromine is associated more frequently with tyramine reactions than phenelzine or isocarboxazid [70, 71]. Selegiline is unlikely to produce

Fig. 2 Synthesis and metabolism of tyramine. Reaction 1: decarboxylation of tyrosine in liver and gastrointestinal tract. Reaction 2: oxidative deamination of tyramine by monoamine oxidase (MAO) in liver, kidney, and other

tissues. Reaction 3: β -oxidation of tyramine by dopamine β -hydroxylase (DBH) located in synaptic vesicles within terminal of sympathetic neurons (From Moore [84])

Fig. 3 Acute response to ingestion of tyramine (a); tolerance to repeated ingestions of tyramine (b); long-term treatment with a monoamine oxidase inhibitor (MAOI)

(c); effects of tyramine after long-term MAOI pretreatment (d). The relative increase in blood pressure denoted by the number of arrows (From Moore [84])

a tyramine reaction if taken at therapeutic doses because of its selective inhibition of MAO-B. Tyramine is an indirect sympathomimetic and is structurally similar to amphetamine. As with most indirect sympathomimetics, tyramine enters the presynaptic neuron through amine uptake pumps [70]. When inside the neuron, tyramine is capable of releasing presynaptic stores of norepinephrine and to a lesser degree serotonin and dopamine (Fig. 3) [71]. Tyramine also can displace epinephrine from the adrenal gland.

Tyramine is found in more than 70 foods and beverages. Any one of these sources may trigger a reaction [71]. Tyramine is the basis for the so-called cheese reaction because aged cheese contains a large amount of tyramine. In similar fashion, broad (fava) beans contain large quantities of dopamine, a mixed-acting sympathomimetic compound. Patient compliance to an MAO inhibitor–restrictive diet has been reported to be less than 30% of patients [70]. In addition, approximately 4–8% of compliant patients

experience a tyramine reaction during their therapy [70]. Nonetheless, newer MAO inhibitor treatment guidelines call for avoiding only a few high-risk food groups, such as nonfresh meat or fish, sauerkraut, aged meats and cheeses, Chianti wine, vermouth, pickled herring, concentrated yeast extracts, and broad beans [70, 71].

The tyramine reaction characteristically occurs within 15–90 min after ingesting the dietary amine. The severity of this reaction is highly variable and partially related to the total amount of tyramine ingested [70, 71]. The hallmark symptom of tyramine reactions is a severe occipital or temporal headache [68]. Other associated symptoms include hypertension, palpitations, diaphoresis, mydriasis, neck stiffness, pallor, neuromuscular excitation, and chest pain [68]. Most symptoms gradually resolve over 6 h without specific therapy. Fatalities have been reported, although rarely since 1967, and usually are due to intracranial hemorrhage or myocardial infarction [38]. An electrocardiogram should be

obtained for all patients with tyramine-associated chest pain. Focal neurological findings or a persistent severe headache warrants investigation with a computed tomography scan of the head.

Tyramine Reaction

Diagnosed by rapid onset of headache and hypertension after tyramine ingestion

Can occur with other indirect sympathomimetics (e.g., levodopa)

Phentolamine or nitroprusside are preferred antihypertensive agents

Avoid β -blockers because they may worsen hypertension

Persistent headaches should be evaluated for intracranial hemorrhage

Chest pain should be evaluated for myocardial ischemia

Most tyramine reactions rapidly resolve with appropriate treatment

Asymptomatic patients can be discharged after 4 h of observation

Admit all patients symptomatic for at least 8 h after all signs and symptoms resolve

Diagnosis

MAO inhibitor toxicity is a clinical diagnosis based solely on the history of MAO inhibitor ingestion and hyperadrenergic symptoms. There are no readily available confirmatory tests. Special toxicological testing would be of little value in detecting MAO inhibitors because most of the parent compounds have a short half-life in relation to their duration of action and may not be detectable when symptoms develop. The best use of laboratory tests is to assist in the differential diagnosis of MAO inhibitor toxicity and to identify possible complications of MAO inhibitor overdose, which include hypoxia, rhabdomyolysis, renal failure, hyperkalemia, metabolic acidosis, hemolysis, and disseminated intravascular coagulation. Leukocytosis [55] and thrombocytopenia [42, 52, 72] are seen commonly with MAO inhibitor toxicity.

A positive urine drug screen for methamphetamine or amphetamine may be expected with selegiline ingestions because it is metabolized to the levorotatory *l*-methamphetamine and ultimately *l*-amphetamine and may cross-react with some immunoassays designed to detect the dextrorotatory (*d*-) forms typically encountered in illicit methamphetamine abuse [73, 74]. Chiral analysis can be performed if it is imperative to discriminate between therapeutic selegiline and illicit methamphetamine use [73–75]. There are conflicting reports in the literature suggesting that tranlycypromine is metabolized to amphetamine and therefore may yield a positive result on immunoassays for amphetamine [76]. However, there is a growing body of evidence that supports that the cleavage of the cyclopropyl ring of tranlycypromine to form amphetamine does not occur [41–43, 77]. Consequently, tranlycypromine should not result in a positive amphetamine screen [38, 77].

The differential diagnosis of an unknown MAO inhibitor ingestion is extremely challenging and includes all drugs and medical conditions capable of producing a hyperadrenergic state, altered mental status, hyperthermia, or muscle rigidity (Table 2). MAO inhibitor toxicity also could be associated with a sympatholytic presentation, broadening the differential possibilities further. In reality, without a history of exposure, a conclusive diagnosis of MAO inhibitor poisoning cannot be made because no confirmatory tests are available.

Treatment

All patients with MAO inhibitor overdose require immediate physician evaluation, intravenous access, intensive clinical and cardiac monitoring, and possibly gastric decontamination. There are no known antidotes for MAO inhibitor toxicity. There are no controlled human studies on MAO inhibitor overdose treatment on which to base patient management recommendations. Medical management is based on providing excellent supportive care, avoiding potential drug interactions, and treating medical complications early. Onset of

Table 2 Differential diagnosis of monoamine oxidase inhibitor overdose

0, not expected to be present; X, expected in the minority of cases; XX, expected to be commonly present; XXX, expected to be present in almost all cases

toxicity is usually gradual and can be delayed, sometimes 24 h after ingestion. The abrupt development of seizures, coma, respiratory insufficiency, and cardiovascular collapse is possible, however. Certain patient groups, such as patients with underlying medical problems, children, and the elderly, may manifest greater toxicity at a given dose of an MAO inhibitor.

Indications for ICU Admission in Monoamine Oxidase Inhibitor Poisoning

1. Admit all patients who ingested >1 mg/kg to an ICU (possible exception reversible MAO inhibitors).
2. Admit all patients with clinical signs of toxicity <24 h since ingestion.
3. Patients with serotonin syndrome, unless mild.

The utility of gastrointestinal decontamination in MAO inhibitor overdose has never been studied. The following recommendations are general guidelines based on the pharmacokinetic profile of MAO inhibitors and human case reports.

Administration of activated charcoal as a single dose of 1 g/kg is reasonable, particularly if it can be given shortly after ingestion, ideally <1–2 h, and there are no other contraindications. The efficacy of treatment with activated charcoal treatment, if any, is expected to decrease as time passes post ingestion. It is important to highlight that there are no studies demonstrating that activated charcoal administration alters the outcome of patients with MAO inhibitor overdoses. Caution must be exercised when giving patients activated charcoal after they have ingested drugs that may cause altered level of consciousness. Multiple-dose activated charcoal administration is not expected to be advantageous. Historically, some medical toxicologists recommend gastric lavage for significant irreversible MAO inhibitor ingestions if it can be performed within 1 h after ingestion because of the high risk of mortality. It is unknown whether this intervention alters the clinical course or outcome in MAO inhibitor overdose. There are no studies to suggest that gastric lavage improves the outcome in poisoned patients and this procedure has been largely abandoned. Because MAO inhibitors are absorbed rapidly,

delayed gastric lavage, or whole-bowel irrigation, is unlikely to be of any clinical benefit and is not recommended. Routine laboratory tests should be performed on all patients, with particular emphasis on identifying complications such as hyperkalemia, metabolic acidosis, and rhabdomyolysis.

Hypertension

Acutely hypertensive patients should be treated with short-acting intravenous antihypertensive agents because of the potential to develop precipitous hypotension. In most cases, an intra-arterial catheter is required for accurate blood pressure monitoring. Traditionally, the antihypertensive agents of choice are α -antagonists or direct-acting vasodilators such as phentolamine or nitroprusside (Level of Evidence [LoE] III). Phentolamine is a nonspecific α -adrenergic receptor antagonist, usually administered as a 2.5–5.0-mg bolus followed by a continuous infusion (1–5 mg/h) titrated until blood pressure elevation is controlled. Phentolamine use commonly is associated with reflex tachycardia. Nitroprusside is given as a continuous infusion with an initial rate of 1 μ g/kg/min, and titrated according to blood pressure response. Prolonged high doses of nitroprusside can predispose to cyanide toxicity (see ► Chap. 40, “Sodium Nitroprusside”) although this is rarely encountered due to the routine addition of thiosulfate to nitroprusside infusions. Nitroglycerin can also be used to control hypertension and may be effective for the relief of cardiac-related chest pain. β -Blockers pose a theoretical risk of increasing the blood pressure through unopposed α -adrenergic receptor-mediated vasoconstriction and should be considered contraindicated (LoE III). Despite its α -receptor blocking ability, labetalol should also be avoided as its β -receptor blockade is much greater than its α -blockade (3:1 oral; 7:1 IV). Because patients with MAO inhibitor toxicity may change rapidly from being hypertensive to being hypotensive, short-acting antihypertensive agents are preferable.

Hypotension

Hypotension carries a poor prognosis in MAO inhibitor overdose [46, 51]. Isotonic intravenous fluid boluses of 10–20 mL/kg are the initial treatment of hypotension. When vasopressors are required, only direct-acting sympathomimetics should be utilized. Norepinephrine is the vasopressor of choice, with epinephrine as the second drug of choice (LoE III). Patients with MAO inhibitor toxicity may have increased sensitivity to vasopressors, and lower starting doses are recommended. (LoE III) It is important to avoid all agents with indirect sympathomimetic actions (e.g., dopamine) and choose from available direct-acting agents instead (Table 3). In general, indirect sympathomimetics can act synergistically with MAO inhibitors to produce an exaggerated hyperadrenergic response, producing excessive rise in blood pressure. Therefore, the use of dopamine should be avoided. Its vasopressor effect may be absent due to neuronal and cytoplasmic depletion of norepinephrine leaving its action at peripheral dopamine and β -adrenergic receptors unopposed resulting in vasodilation and worsening hypotension.

Dysrhythmias

Sinus tachycardia rarely requires specific drug therapy, unless it is producing myocardial ischemia. Lidocaine, or procainamide, are the most likely effective antiarrhythmics in treating MAO inhibitor-induced dysrhythmias [46]. (LoE III) Amiodarone may be a reasonable alternative option but little evidence is available regarding its use in the management of tachydysrhythmias from MAO inhibitor toxicity. Hemodynamically significant bradycardia may develop and can degrade quickly into asystole in the later stages of the overdose [51]. Pharmacological treatment of bradycardia includes atropine, isoproterenol, and dobutamine. Transvenous or transcutaneous pacing may be necessary in severe or refractory bradycardia.

Table 3 Drugs contraindicated with monoamine oxidase inhibitors

Indirect-activity and mixed-activity sympathomimetics	Antidepressants	Miscellaneous drugs
Benzphetamine	Amoxapine	Atomoxetine
Bretylium	Amitriptyline	β -Blockers
Caffeine	Bupropion	Buspirone
Cocaine	Citalopram	Carbamazepine
Dexfenfluramine	Clomipramine	Clonidine
Dextroamphetamine	Desipramine	Cyclobenzaprine
Diethylpropion	Desvenlafaxine	Dextromethorphan
Dopamine	Doxepin	Disulfiram
Ephedrine	Duloxetine	Ergot Alkaloids
Fenfluramine	Escitalopram	Fentanyl
Guanethidine	Fluoxetine	Furazolidone
Isometheptene	Fluvoxamine	Ginseng
Mephentermine	Imipramine	Ketamine
Metaraminol	Maprotiline	Levodopa
Methamphetamine	Milnacipran	Linezolid
3,4-Methylenedioxymethamphetamine (MDMA)	Mirtazapine	Lithium
Methyldopa	Nefazodone	Meperidine
Methylphenidate	Nortriptyline	Methylene blue
Pemoline	Paroxetine	Oral hypoglycemic agents
Phentermine	Sertraline	Phenothiazines
Phencyclidine	St. John's wort	Procarbazine
Phenylpropanolamine	Trazodone	Rizatriptan
Propylhexedrine	Venlafaxine	Sumatriptan
Pseudoephedrine	Vilazodone	Tapentadol
Reserpine	Vortioxetine	Tramadol
Ritodrine		Tryptophan
Theophylline		Zolmitriptan
Tyramine		

Seizures

Benzodiazepines are considered first-line therapy in treating MAO inhibitor-induced seizures [46, 56]. (LoE III) Other GABA-A agonists such as barbiturates (i.e., phenobarbital) or propofol are likely also effective in controlling seizures due to MAO inhibitor toxicity [46, 56]. Clinicians should be aware that all of these agents may cause or worsen hypotension, especially at higher doses. Phenytoin is ineffective in stopping drug-induced seizures and is not recommended in cases of MAO-inhibitor-induced seizure activity (see ► Chap. 20, “Toxicant-Induced Seizures”). General anesthesia

with muscle paralysis may be necessary in cases of status epilepticus to prevent the metabolic acidosis, hyperthermia, and rhabdomyolysis commonly seen with persistent seizure activity. When muscle paralysis is used to control the peripheral manifestations of seizure activity, electroencephalographic monitoring is necessary to assess for the presence of central nervous system seizures. Muscle paralysis is accomplished best using nondepolarizing neuromuscular blocking agents (e.g., vecuronium). (LoE III) Succinylcholine should not be utilized in cases of severe MAO inhibitor toxicity as patients are often hyperthermic with rhabdomyolysis and may be at increased risk of hyperkalemia and

subsequent dysrhythmias. (LoE III) Furthermore, phenelzine lowers pseudocholinesterase activity and may prolong the action of succinylcholine [78].

Hyperthermia

Close and accurate monitoring of core body temperature is indicated in patients with MAO inhibitor toxicity. Rapid and aggressive cooling is required in patients with hyperthermia. First-line therapy includes titration of benzodiazepines, or other GABA-A agonists such as phenobarbital (LoE III), which results in centrally mediated reduction in muscle hyperactivity leading to decreased heat production. This coupled with increasing evaporative and conductive heat loss is essential for the successful treatment of hyperthermia. Increasing heat loss is accomplished best by using ice baths and cool mist spray with fans. Hyperthermia often is resistant to these measures in the setting of persistent muscle rigidity. Consequently, muscle paralysis with nondepolarizing agents should be performed when diffuse rigidity is refractory to benzodiazepine or other GABA-A agonist therapy. Dantrolene use has been reported with apparent success as a muscle relaxant in resistant cases of muscle rigidity [42, 46]. (LoE III) Prior to institution of nondepolarizing neuromuscular blockade, use of dantrolene can be considered in cases in which muscle rigidity is not fully controlled by titration of GABA-A agonists (i.e., benzodiazepines, phenobarbital, or propofol). Antipyretics generally are ineffective in the treatment of drug-induced hyperthermia, and other temperature reduction methods are necessary.

Admission Criteria

All intentional MAO inhibitor overdoses and accidental exposures of greater than 1.0 mg/kg require admission to an ICU. (LoE III) Accidental exposures of less than 1.0 mg/kg still require hospital admission to a monitored bed; however,

these patients are unlikely to develop life-threatening complications. Reversible MAO inhibitors are less toxic than traditional MAO inhibitors, and ingestions of less than 2,000 mg in adults are unlikely to produce significant toxicity. Asymptomatic patients can be admitted to a monitored bed for 24-h observation. Even a single MAO inhibitor tablet may produce life-threatening drug interactions, such as the serotonin syndrome, or other drug interactions under certain circumstances. Asymptomatic patients should be monitored for at least 24 h before medical clearance. Vital sign abnormalities should be recognized early and treated appropriately. Dietary and medication restrictions should be followed meticulously during hospitalization. All patients should be instructed to avoid contraindicated foods and medications for a minimum of 2 weeks. Consultation with a medical toxicologist is recommended. If one is not locally available assistance can be obtained from poison control centers. Patients requiring transfer to hospitals with ICU capabilities should be transferred as soon as possible to avoid the problems anticipated with delayed onset of toxicity. Medical personnel capable of performing advanced cardiac life support and endotracheal intubation should accompany all patients being transferred.

Extracorporeal Removal Techniques

Hemodialysis, hemoperfusion, and peritoneal dialysis have no established role in the treatment of MAO inhibitor poisoning. Hemodialysis should only be used for typical indications such as severe, refractory acidosis, hyperkalemia, or acute renal failure which may be complications of severe MAO inhibitor toxicity.

Tyramine Reaction

In cases of severe hypertension, an α -antagonist or direct-acting vasodilator are the drugs of choice. (LoE III) Phentolamine is typically given

intravenously in 2.5–5 mg doses every 5–15 min until the blood pressure is controlled. The half-life of phentolamine is approximately 20 min, and its duration of action is less than 1 h. Nitroprusside is another rapidly acting direct vasodilator and is administered as a continuous infusion (1–4 µg/kg/min). In cases of moderate hypertension, nifedipine and prazosin have been reported to be effective [46, 68]. (LoE III) β-Adrenergic blocking drugs generally are considered contraindicated because of the risk of unopposed α-receptor stimulation. Hospital admission should be strongly considered for patients whose hypertension does not resolve completely within 6 h after onset. Gastrointestinal decontamination is unlikely to offer any significant benefit because the onset of toxicity is so rapid after tyramine exposure. Tyramine reactions are immediate, without delayed sequelae. Asymptomatic patients require only 6 h of observation.

Criterion for ICU Discharge in Monoamine Oxidase Inhibitor Poisoning

Stable patient who is at least 24 h post ingestion

Drug Interactions

Long-term MAO inhibitor drug therapy predisposes to many potentially significant drug interactions (see Table 3). Documentation of human MAO inhibitor drug interactions often is limited to single case reports or case series. Controlled human studies are impractical owing to the severe and potentially life-threatening nature of these reactions. Animal studies often have limited applicability to human toxicity. Patients taking MAO inhibitors should not receive other prescription or nonprescription medications unless strongly warranted and only after drug compatibility with MAO inhibitors has been confirmed (Table 4).

Drug interactions involving MAO inhibitors can be grouped into three categories – pharmacodynamic, pharmacokinetic, and idiosyncratic. The most common pharmacodynamic reaction

Table 4 Drugs considered safe with monoamine oxidase inhibitors^a

Direct-activity sympathomimetics	Miscellaneous drugs
Albuterol	Acetaminophen
Dobutamine	Aspirin
Epinephrine	Barbiturates
Fenoldopam	Benzodiazepines
Isoproterenol	Calcium channel blockers
Norepinephrine	Cephalosporins
Terbutaline	Corticosteroids
	Inhalational anesthetics
	Lidocaine
	Morphine ^b
	Nitroglycerin
	Nitroprusside
	Nitrous oxide
	Nonsteroidal antiinflammatory drugs
	Penicillin
	Phentolamine
	Procainamide

^aAlways use the lowest effective dose
^bSome commonly available drug interaction resources suggest an interaction between morphine and phenelzine based on weak evidence and without mechanistic explanation [85]

involves drugs with indirect sympathomimetic actions [68, 79], such as amphetamine, methamphetamine, pseudoephedrine, and ephedrine. These drugs have the potential to produce a hyperadrenergic condition similar to the tyramine reaction and can be found in over-the-counter preparations, drugs of abuse, and some prescription products. Pharmacokinetic drug interactions have been noted with MAO inhibitors because they are metabolized through the cytochrome oxidase enzyme system and can inhibit the hepatic metabolism of other drugs. The potentiation of opiate and sedative-hypnotic drugs is an example of this type of enzyme inhibition [68]. Phenelzine is metabolized in part via acetylation; as a result slow acetylators of hydrazines may be at increased risk for adverse drug effects of phenelzine. Phenelzine is also a relatively weak inhibitor of CYP 2C19 and CYP 3A4, but the clinical relevance is unclear [38].

Tranylcypromine is a potent highly selective competitive inhibitor of CYP 2A6 [38]. Tranylcypromine and phenelzine have been shown to increase insulin release and predispose to hypoglycemia, especially in patients taking oral sulfonylurea agents [68, 80, 81]. Insulin dosage also may warrant reduction.

Serotonin syndrome is a potentially life-threatening idiosyncratic reaction. It most commonly occurs when MAO inhibitors are combined with other serotonergic agents [82, 83]. A complete description of serotonin syndrome and a listing of serotonergic medications can be found in ► Chap. 24, “Serotonin Syndrome” [68]. Given the relative high-frequency use of opioids, special mention is warranted regarding agents such as tramadol, tapentadol, meperidine, and dextromethorphan which may produce serotonin syndrome in combination with MAO inhibitors [78]. All pro-serotonergic medications are contraindicated for 2 weeks after discontinuation of an irreversible MAO inhibitor. (LoE III) This recommendation is particularly important to prevent the development of serotonin syndrome.

Equally important is the recognition that certain medications are generally compatible with MAO inhibitors (see Table 4). Aspirin, acetaminophen, ibuprofen, and morphine have been used in combination with MAO inhibitors without complications [68]. It should be noted that some commonly available drug-drug interaction resources suggest there is a potential interaction between morphine and phenelzine. The nature and basis of the interaction is unclear. Some sources indicate potentiation of opioid effects specifically CNS/respiratory depression. While there is an unconvincing case report implicating this combination in the development of serotonin syndrome [85]. No plausible mechanism was identified. Direct-acting sympathomimetic agents, such as norepinephrine, can be used with caution, using lowest possible effective dose. Direct sympathomimetics do not rely on the release of neurotransmitters for their activity and are inactivated by catechol *O*-methyltransferase, which is unaffected by MAO inhibitors [68].

Key Points in Monoamine Oxidase Inhibitor Poisoning

1. Clinical toxicity often is delayed 6–24 h after ingestion.
2. MAO inhibitors are not detected by common drug tests.
3. Drug concentrations are not useful for managing overdose patients.
4. Selective, reversible MAO inhibitors are less toxic than irreversible MAO inhibitors.
5. MAO inhibitors have little effect on the electrocardiogram except for sinus tachycardia.
6. Consider serotonin syndrome in patients taking two or more serotonergic agents.
7. Admit all patients who ingested >1 mg/kg for 24 h of observation.
8. Do not use β -blockers to treat tachycardia or hypertension.
9. Do not use indirect sympathomimetics.
10. Avoid combining serotonergic agents.
11. Do not give meperidine, tramadol, or dextromethorphan to patients taking MAO inhibitors.
12. Extracorporeal removal is an unproven modality in MAO inhibitor overdose.
13. Selegiline is metabolized to methamphetamine.
14. Tranylcypromine does not produce amphetamine in the urine.

While many drugs have some effect on serotonergic receptors this chapter focuses upon the toxicity seen with medications whose primary antidepressant therapeutic mechanism of action is to modify serotonergic transmission. This includes selective serotonin reuptake inhibitors (SSRI), serotonin noradrenergic reuptake inhibitors (SNRI), and tetracyclic and triazolopyridine antidepressants (Tables 1, 2, 3, and 4).

The release of serotonin into the synapse from presynaptic vesicles follows depolarization and influx of calcium into the cell. Presynaptic serotonin concentrations are maintained by both presynaptic synthesis from precursors such as tyramine and by the reuptake of serotonin from the synapse. Serotonin homeostasis is maintained by metabolism by monoamine oxidase inhibitors. Presynaptic reuptake utilizes biogenic amine reuptake transporters for both serotonin and also noradrenaline [1]. Reuptake inhibitors such as SSRI and SNRI block the amine transporter at similar locations but with some variation of binding substrates and affinity [2].

The impetus for the development of primarily serotonergic drugs came from observations of efficacy of clomipramine compared with other tricyclic antidepressants in some patients. This efficacy was ascribed to relatively greater serotonin reuptake inhibition of clomipramine compared with most other tricyclic antidepressants. This led to more specific receptor targeted drug development leading to the prototypical SSRI fluoxetine. Subsequent development also

^cAvailable in some countries in an extended release form

encompassed screening for cardiotoxicity and the introduction of compounds with lower likelihood of significant pharmacokinetic interactions [3].

The overall use of serotonergic antidepressants greatly exceeds the population estimates for their major therapeutic indications [4]. As a group their higher safety in overdose and different side effect profile compared with tricyclic antidepressants has contributed to their high volume of use. As a consequence, serotonergic antidepressants are commonly taken in deliberate self-poisoning. The North American National Poison Data System reports frequent hospital presentations but low morbidity and mortality for these agents [5]. These observations and evidence of different relative toxicity within the groups are also supported by fatal toxicity indices (FTI) which are calculated from deaths per million prescriptions. The FTI for venlafaxine 13.2 (CI 9.2 to 18.5) is significantly higher than that of SSRIs and the tetracyclic antidepressants (point estimates ranging from 0.7 to 3.3) [6]. This is consistent with clinical observations of severity [6–9].

Toxicity is most commonly seen following deliberate self-poisoning but may also be seen in the context of significant drug-drug interactions and to a lesser extent drug-disease interaction. In single agent ingestions the overall risk of morbidity and mortality is low, but there is significant variation in the relative risk of toxicity between the four drug classes and within some drug classes. Within this group SNRIs are the most likely to require intensive care admission. Specific clinical assessment and management focuses upon the detection of serotonin toxicity (see ► Chap. 24, “Serotonin Syndrome”), cardiovascular toxicity, and neurological toxicity.

SSRIs

Biochemistry and Clinical Pharmacology

SSRIs are a chemically diverse group of lipid soluble compounds (Table 1). Their principle route of elimination is hepatic, predominantly by

Table 2 Therapeutic pharmacokinetics NSRI

Agent (Chemical class)	Defined daily dose (mg)	Bioavailability (%)	Protein binding %	Vd L/kg	Tmax (hrs)	Elimination	T1/2 (hrs)	Notes

cytochrome P450. Fluoxetine and paroxetine cause clinically important inhibition of some cytochrome enzymes (Table 1) [10]. At steady state the half-life is less than 2 days for all the SSRIs with the exception of fluoxetine and its active metabolite norfluoxetine (half-life 7–15 days). In therapeutic doses sertraline and citalopram show linear and fluoxetine, fluvoxamine, and paroxetine nonlinear pharmacokinetics. In overdose it is likely that all would show nonlinear elimination kinetics (Table 1).

Inhibition of presynaptic reuptake of serotonin increases synaptic serotonin and agonism at the 5HT_{1a} receptor which is thought to mediate much of the antidepressant effects of SSRIs. Serotonin reuptake inhibition by SSRIs is significantly higher than inhibition of dopamine or norepinephrine reuptake. There are no other reported clinically significant direct effects on other

neuroreceptors [10]. Paroxetine has some muscarinic receptor antagonism which is significantly less than that seen with clomipramine and of doubtful clinical significance [11].

Pathophysiology of Toxic Effects

The serotonin syndrome is the most commonly seen toxicity of SSRIs and relates directly to the extent of inhibition of serotonin reuptake. The major variation in toxicity within the class is seen with citalopram and escitalopram. Inhibition of repolarization of myocardial cells by blocking potassium efflux channel's coded for by the HERG gene causing QT prolongation and an increased risk of Torsades de Pointes is reported for SSRIs but the risk is highest for citalopram and escitalopram [12–14].

Clinical Presentation and Life-Threatening Complications

Overall the risk of death or significant morbidity from single SSRI ingestions is low. The most frequent specific clinical findings are signs of serotonin syndrome. All patients should be assessed for QT prolongation; the risk is significantly higher for ingestions of citalopram and escitalopram. Within intensive care units patients with SSRI ingestions are most commonly seen in the context of multiple drug ingestion.

Serotonin Syndrome

Clinically, the serotonin syndrome comprises a cluster of clinical effects producing a spectrum of severity. While the syndrome is common it is unusual to see significant toxicity that requires treatment in intensive care. The syndrome is attributed to serotonin agonism at the 5HT_{2a} receptor. The severity of SSRI-induced serotonin syndromes is dose related and reflects the synaptic serotonin concentration. Ingestion of two or more additive or synergistic serotonergic agents has a higher risk of severe toxicity than ingestion of a single agent [15]. An example of the effects of such synergism is the co-ingestion of therapeutic doses of a monoamine oxidase inhibitor and a SSRI.

The most common clinical signs are those associated with a mild serotonin syndrome, specifically brisk reflexes and poorly sustained clonus. The risk of toxicity from ingestion of a single SSRI increases with dose but there does not appear to be any within class difference in the risk of serotonin toxicity. Serotonin syndrome was seen in 14% of 469 individuals with self-poisonings with single SSRIs in a prospective single center consecutive case series. No patients developed serotonin syndrome that required ICU admission [14]. Within this cohort a GCS of <9 was seen in 11 patients, 10 of whom had co-ingested sedative medication. Short self-limited generalized seizures were seen in 1.9% of patients, but there was no apparent difference within the class.

Cardiovascular

The potential for significant cardiac toxicity manifests as QT prolongation is dose related, and the

highest risk is for citalopram and escitalopram [14, 16–22]. Torsades de pointes has been reported for both citalopram and escitalopram, but the overall risk is low [23, 24]. QT prolongation and torsades de pointes have been reported with fluoxetine [13].

The low risk of torsade is also supported by observational studies reporting three deaths in 5,251 patients with citalopram overdose [12]. Citalopram is associated with the higher risk of death than other SSRIs [25]. The risk of QT prolongation increases with ingestions of more than 600 mg citalopram and 300 mg of escitalopram but may not be manifest for 12 h [16, 20]. Patients with prolonged QT at admission or with ingestions of more than 600 mg citalopram or 300 mg of escitalopram require continuous ECG monitoring for at least 12 h. In those patients with QT prolongation monitoring should continue until the QT normalizes. Magnesium, potassium, and calcium should be checked and corrected if low (see ► Chap. 22, “Toxicant-Induced Torsade de Pointes”).

The tachycardia commonly seen in serotonin toxicity can complicate the assessment of QT prolongation by overestimating the QTc. Detection of prolonged QT is best assessed using the Fossa nomogram especially in the presence of tachycardia rather than using QTc calculations [26, 27] (Grade II-2 recommendation).

Diagnosis

Diagnostic algorithms for a categorical diagnosis of serotonin syndrome have been developed, validated, and widely used [28] (Fig. 1). However, treatment is normally based upon an assessment of severity of the syndrome, and so patients require repeated physical examinations focusing upon the severity and duration of clonus, presence of fever, and respiratory failure [15] (see ► Chap. 24, “Serotonin Syndrome”).

Treatment

Serotonin Syndrome

Specific treatment in patients with mild to moderate serotonin syndrome is often not required. Most

Fig. 1 Hunter criteria for serotonin toxicity (Figure used under a Creative Commons license from wikitoX.org)

patients with agitation, tremor, or unsustained clonus will gain symptomatic relief from benzodiazepines or 5HT_{2a} antagonists such as cyproheptadine titrated against clinical effects. Severe serotonin toxicity manifesting as fever, spontaneous sustained clonus, and hypercapnic respiratory failure is rare in ingestions of single agents but is an indication for ICU admission (see ► Chap. 24, “Serotonin Syndrome”).

Decontamination

Administration of activated charcoal up to 4 h after ingestion reduces the risk of QT prolongation following ingestion of either citalopram or escitalopram [18, 20, 22]. Suggested thresholds for decontamination are more than 600 mg citalopram or 300 mg of escitalopram [16, 20]. While it is likely that decontamination would reduce the rate and severity of serotonin syndrome, it is not warranted in single agent SSRI ingestions. Decontamination should be considered in patients who meet criteria for ICU

admission and in particular if they have taken multiple serotonergic synergistic medications.

QT Prolongation

Correction of hypokalemia, hypocalcemia, and hypomagnesemia is indicated in patients with true prolongation of the QT interval (see ► Chap. 22, “Toxicant-Induced Torsade de Pointes”) [26]. Given the relatively low risk of TdP associated with most of these agents, there is little reason to give magnesium to patients who are not magnesium deficient [29].

NSRIs (SNaRIs)

Biochemistry and Clinical Pharmacology

The bicyclic serotonin and noradrenaline reuptake inhibitor (SNRI or NSRI) antidepressants venlafaxine and desvenlafaxine are

phenylpropylamines that are structurally and pharmacologically related to the nonopioid analgesic tramadol but not to any conventional antidepressant medications. Duloxetine is chemically distinct containing a naphthalene moiety, which consists of two fused benzene rings. NSRIs are potent inhibitors of neuronal serotonin and noradrenaline reuptake and weak inhibitors of dopamine reuptake. They have no notable monoamine oxidase inhibitor activity and minimal affinity for muscarinic, cholinergic, histamine, or α_1 - and α_2 -adrenergic receptors.

The pharmacokinetics of NSRIs in therapeutic use is summarized in Table 2. Both venlafaxine and desvenlafaxine are available in extended release which prolongs the absorption phase producing a later T_{Max} and also increasing the apparent half-life. A study based on 76 self-poisonings with extended release venlafaxine showed the mean half-life in overdose to be 12.9 h [30].

Pathophysiology of Toxic Effects

The most commonly seen toxicity is an extension of the therapeutic effect of blocking amine reuptake. Both synaptic serotonin and noradrenaline concentrations are increased. The combination of signs produced by both synaptic serotonin excess and a noradrenaline excess-induced sympathomimetic syndrome contributes to satisfying the diagnostic criteria for serotonin toxicity [28]. This may explain the higher rates of serotonin toxicity seen in cohort studies that compare NSRI with SSRI [31, 32].

At high doses there is evidence of cardiac sodium channel blocking leading to delayed depolarization. Duloxetine blocks persistent late Na currents preferentially [33]. Animal models suggest venlafaxine cardiotoxicity and QRS widening are due to dose dependent Na⁺ channel blockade in the resting state [34]. Mild systolic hypertension is reported in venlafaxine and desvenlafaxine [9, 35]. Hypotension is reported following large ingestions of venlafaxine and is attributed to reduced myocardial contractility [36]. Venlafaxine and desvenlafaxine have been associated with Takotsubo

cardiomyopathy in both therapeutic doses and in overdose [37, 38].

The mechanism of seizures is not well defined. Hypoglycemia responsive to octreotide has been reported [39].

Clinical Presentation and Life-Threatening Complications

As venlafaxine is the prototypical drug of this class, published experience of effects in overdose is greater than its active metabolite desvenlafaxine or duloxetine. Available data does not suggest significant differences in toxicity within this class [40, 41].

Venlafaxine has higher rates of serotonin toxicity, seizures, and prolongation of the QRS complex than seen in SSRI [32]. Onset of toxicity may be delayed for a significant period of time for extended release preparations [32]. Death from cardiovascular complications is reported [36, 42, 43].

Rhabdomyolysis with creatinine kinase greater than 1,000 was noted in 3.8% of venlafaxine poisoning and appeared in patients with or without seizures [44].

Serotonin Syndrome

Serotonin syndrome occurred in 30% of patients in a consecutive series of venlafaxine poisoning [9, 31]. While a diagnosis of serotonin syndrome is not necessarily an indication for specific treatment, it is dose related and may identify a group of patients at greater risk of seizures and/or cardiovascular toxicity [44].

Central Nervous System Effects

Sedation is seen in large overdoses and probably is due to histamine antagonism [45]. The most common central nervous system (CNS) effects are agitation as part of the spectrum of serotonin toxicity and seizure activity [9]. While the mechanism of seizure activity is unclear there is a clear dose related risk.

A consecutive case series of patients who ingested venlafaxine found an overall incidence of usually self-limited seizures of 5–8.9% [44, 46]. Most seizures occurred within 16 h of ingestion but may potentially occur for up to 24 h. The probability of seizures was dose related (Table 5)

Table 5 Probability of seizures from venlafaxine in adult patient [46]

Venlafaxine dose (mgs)	Median probability of seizures (95% credible interval)
1,000	0.05 (0.03–0.08)
5,000	0.19 (0.09–0.35)
10,000	0.75 (0.30–0.96)

and was reduced by gastrointestinal decontamination with activated charcoal [46].

A poison center study reported seizures occurring in 6.9% of duloxetine ingestions and were only seen at doses greater than 1,800 mg [41].

Cardiovascular

A review of 369 venlafaxine presentations in 273 patients with a median ingested dose of 1,500 mg (range 75 mg to 13,500 mg) showed that only minor cardiovascular effects were observed [47]. Tachycardia was noted in 54% of presentations, 40% had a systolic BP >140 mmHg, 5% had a systolic BP < 90 mmHg. Comparable rates of hemodynamic changes were confirmed in another case series [35]. Prolonged QT intervals were observed in 6% of patients. A QRS duration > 120 ms occurred in 7% of patients, all of whom had ingested over 5 g [47]. Batista reports a consecutive series of 80 patients with venlafaxine ingestions. Four developed acute heart failure, all following ingestions of over 3,000 mg. Three of these four died. Echocardiography showed diffuse left ventricular dysfunction [36]. Other reports of death or acute cardiomyopathy have all been in doses of greater than three grams [36, 43, 48, 49]. However, the specificity and sensitivity of a threshold dose has not been established as significant toxicity has been reported through all dose ranges. Takosubo cardiomyopathy has been associated with overdose and therapeutic doses of venlafaxine and desvenlafaxine, including one patient who developed torsade de pointes [37]. Takosubo cardiomyopathy was associated with QT prolongation and with torsade de pointes, although most patients who have developed this arrhythmia had multiple risk factors. In a case series of 75 desvenlafaxine overdose, 32% showed mild hypertension and 39% sinus tachycardia, no patients had seizures or a QRS duration that exceeded 120 msec [50].

Diagnosis

The clinical assessment and diagnosis of NSRI toxicity is typically made on the basis of the history and clinical setting. Patients should have repeated assessment for serotonin toxicity, and those who develop signs of severe toxicity should be assessed for respiratory failure and rhabdomyolysis. Patients with serotonin toxicity are more likely to develop other significant toxicity in the author’s experience. For patients who develop a QRS duration monitoring is indicated until their ECG returns to normal. In practice, these patients normally have other signs of toxicity. Patients with hypotension that does not respond to intravenous fluid administration should have an echocardiogram to assess myocardial function. There is an association of QT prolongation with Takotsubo cardiomyopathy [50].

Treatment

For most patients who have overdosed on an NSRI their clinical course will be uncomplicated, and they are unlikely to require intensive care admission.

Patients with a reduced level of consciousness who require intubation should receive a single dose of activated charcoal. A single dose of activated charcoal reduced venlafaxine bioavailability by 29% and increased clearance by 35% [46]. Gastrointestinal decontamination with activated charcoal reduces significant clinical toxicity for ingestions of more than 1,000 mg of venlafaxine [46] (Grade II-2 recommendation).

While QRS widening is relatively common after NSRI overdose significant arrhythmias are rare in ingestions of less than 8 g of venlafaxine [47]. As all the compounds in this class are weak bases and ECG changes are consistent with sodium channel blockade, it seems logical to treat significant tachy- or bradyarrhythmias with plasma alkalization as first line therapy (see ► Chap. 39, “Sodium Channel-Blocking Antidysrhythmics”). There are three cases reported where QRS widening responded to sodium bicarbonate [42, 51] (Grade III recommendation).

Seizures associated with NSRI toxicity are generally self-limited but can be recurrent. The preferred agents to treat drug-induced seizures are benzodiazepines or barbiturates [52].

Tetracyclic Antidepressants

Biochemistry and Clinical Pharmacology

Mirtazapine and mianserin are potent presynaptic antagonists of central alpha adrenoreceptors ($\alpha_2 > \alpha_1$), promoting monoamine release (noradrenaline and serotonin), while not blocking their reuptake. Mirtazapine is an antagonist at both 5-HT_{2a} and 5-HT₃ receptors which attenuates potential serotonin toxicity. It has also been suggested effects on increasing serotonergic function are weak and not contributing significantly to mirtazapine's therapeutic effects [53]. Mirtazapine is also a potent antihistamine leading to sedation and has weak antimuscarinic activity [54].

The pharmacokinetics in therapeutic doses are summarized in Table 3. Both have a high first pass metabolism. It is likely that following overdose the first pass metabolism is saturable leading to increased bioavailability.

Pathophysiology of Toxic Effects

Sedation due to histamine antagonism is the major toxic effect.

Clinical Presentation and Life-Threatening Complications

Mirtazapine

Deaths from mirtazapine poisoning appear to be very rare and comparable to SSRI in fatal toxicity index (FTI) [6] and in poison control data [12]. These observations of low toxicity have been supported by clinical and poison center case series to show minimal effects other than tachycardia, mild hypertension, and minor CNS depression [55–58].

Berling et al. reviewed 89 single agent mirtazapine ingestions and showed the lowest GCS was 10, all within 6 h, with no complications or need for ICU admission. There were no cases of seizures, serotonin toxicity, delirium, or QT prolongation reported in case series [55, 57]. The lack of serotonin toxicity may be explained by the 5HT_{2a} antagonism.

Mianserin

Data on mianserin are even more limited than that for mirtazapine but qualitatively similar. The fatal toxicity index is comparable to mirtazapine [6]. A few patients with serious arrhythmias (heart block and ventricular fibrillation) have been reported but other toxic effects are usually minor [59–61]. One hundred consecutive cases of mianserin hydrochloride poisoning were followed-up by a Poisons Information Service. When mianserin was the only drug ingested, effects were mild and neither deep coma nor convulsions were reported [62, 63]. Although mianserin may rarely cause agranulocytosis, this does not appear to be a dose-related effect [64].

Diagnosis

There are no diagnostic features on physical examination or investigation. The major anticipated toxicity is sedation and potential airway compromise. Significant neurological or cardiac toxicity should prompt assessment for other co-ingestions or other etiologies.

Treatment

Treatment is supportive.

Triazolopyridines (Phenylpiperazines)

Biochemistry and Clinical Pharmacology

Nefazodone and trazodone are structurally related. Both drugs are weak inhibitors of presynaptic serotonin reuptake, but the effects of this are modulated by antagonism of postsynaptic

5-HT_{1a}, 5-HT_{1c}, and 5-HT₂ receptors [65]. There is no significant effect on norepinephrine uptake. Both compounds are antagonists of histamine and alpha 1-adrenoceptor receptors but there is no significant affinity with other receptors [65, 66].

Nefazodone hydrochloride sale was discontinued in 2003 in some countries due to the small possibility of hepatic (liver) injury, which could lead to the need for a liver transplant or even death. The incidence of severe liver damage is approximately 1 in 250,000–300,000 patient-years [67].

The pharmacokinetics in therapeutic use is summarized in Table 4.

Pathophysiology of Toxic Effects

The risk of death is low with a fatal toxicity index comparable to sertraline [68]. No deaths were reported in a consecutive multicenter case series of 180 cases of trazodone [69]. The major clinical syndrome is impaired level of consciousness, due to histamine antagonism, and hypotension secondary to vasodilation from alpha 1-adrenoceptor antagonism [70]. QT prolongation is reported and is thought to be due to effects on the I_{Kr} current channel [71].

Clinical Presentation and Life-Threatening Complications

The most common sign of acute trazodone poisoning is CNS depression [70]. However, trazodone rarely produces coma or seizures when it is the only drug ingested [5]. **Trazodone**-induced CNS effects show marked improvement within 6 to 12 h after ingestion and almost always are resolved within 24 h [70].

Orthostatic hypotension is the most frequently reported cardiovascular abnormality noted in trazodone overdose and usually responds to fluid administration [70]. Trazodone is rarely associated with QT prolongation, ventricular arrhythmias, and sudden death [71, 72].

Diagnosis

There are no diagnostic features on physical examination or investigation. Patients should be assessed for QT prolongation.

The major anticipated toxicity is sedation and potential airway compromise. Significant neurological or cardiac toxicity should prompt assessment for other co-ingestions or other causes.

Treatment

Treatment is supportive.

Indications for ICU Admission

Severe serotonin toxicity

Seizures

QRS widening

QT prolongation

Ingestion of > 600 mg citalopram or >300 mg escitalopram

Greater than two million Americans suffer from epilepsy, and 10% of the population has at least one convulsion in their lifetime. Phenytoin has been commercially available in the United States since 1938 and had been a first-step anticonvulsant for all types of epilepsy, with the exception of absence seizures. In conjunction with benzodiazepines, phenytoin is efficacious in the acute treatment of status epilepticus [1] and has been used prophylactically after head injury [2]. Phenytoin was used as a class 1B antidysrhythmic agent, particularly in the setting of digoxin toxicity, but it no longer is considered a first-line agent for that indication.

Significant morbidity or mortality are infrequent after intentional oral phenytoin overdose [3]. Hypersensitivity reactions, falls, rapid intravenous administration, and extravasation of the drug into soft tissues are responsible for most phenytoin-related mortality and morbidity. The latter two adverse effects are related directly to the propylene glycol, an alkaline diluent, available in the injectable form of the drug [4]. This diluent and most of the local and cardiovascular effects have been eliminated with the newer phenytoin prodrug preparation fosphenytoin.

In 2014, the American Association of Poison Control Centers reported 2745 phenytoin and 14 fosphenytoin exposure calls, of which 1 was associated with death and 45 had major adverse outcomes [5]. One death was also reported in the 2013 database [6]. Although poison center data are limited, these data at least suggest that

Fig. 1 Chemical structures of anticonvulsant medications

significant morbidity and mortality are rare after acute phenytoin exposure.

Biochemistry and Clinical Pharmacology

Phenytoin, or 5,5-diphenyl-2,4-imidazolidinedione, is similar in chemical structure to the barbiturates but has a five-membered ring (Fig. 1). It is a weak acid with a pK_a of 8.3. To maintain parenteral phenytoin in solution, it is adjusted to a pH of 12.

Pharmacokinetics

Given phenytoin's relatively high pK_a , its solubility is limited at physiologic pH and in gastric acid. Absorption of oral phenytoin is slow and imperfect, particularly after an overdose. Peak serum concentrations occur 3–12 h after a single oral dose. Many factors influence kinetics in overdose (e.g., quantity, coingestions, long-term therapy). Intramuscular phenytoin administration results in local precipitation of the drug with sporadic absorption and is not recommended.

After absorption, phenytoin is distributed with a volume of distribution of 0.6 L/kg, approximating body water. Central nervous system

concentrations equilibrate with concentrations in plasma within 10 min of intravenous infusion and correlate with therapeutic efficacy, whereas myocardial concentrations reach equilibrium with plasma within 30–60 min. Within the central nervous system, concentrations are higher in the brainstem and cerebellum than in the cerebral cortex. [7]

Phenytoin is 90% bound to plasma proteins, principally albumin. The free or unbound form is responsible for the drug's clinical effects. The free phenytoin fraction ordinarily constitutes 10% of the plasma level. The unbound fraction of the drug is greater in patients at extremes of age, pregnant women, patients with renal failure, patients with hypoalbuminemia, patients with hyperbilirubinemia, and individuals taking drugs that compete for phenytoin binding sites (e.g., salicylates, valproate, phenylbutazone, tolbutamide, and sulfisoxazole) [8].

Pharmacokinetics of Phenytoin

Therapeutic range: 10–20 $\mu\text{g/mL}$ (20–40 $\mu\text{mol/L}$)

Free phenytoin concentration: 1–2 $\mu\text{g/mL}$ (2–4 $\mu\text{mol/L}$)

Peak after therapeutic oral dose: 3–12 h

Plasma half-life: 6–60 h

Less than 5% of phenytoin is excreted unchanged in the urine. Most is metabolized by hepatic microsomal enzymes, primarily by cytochrome P450 (CYP) 2C9 and secondarily by CYP2C19. Its major (60–70%) metabolite, the parahydroxyphenyl derivative, is generated by CYP2C9. Inhibitors of CYP2C9 such as amiodarone, fluconazole, fluoxetine, metronidazole, or zafirlukast increase phenytoin serum concentrations. Although CYP2C9 inducers such as phenobarbital and rifampin decrease phenytoin concentrations, inhibitors of CYP2C19 such as cimetidine, felbamate, fluvoxamine, ketoconazole, lansoprazole, omeprazole, paroxetine, and ticlopidine increase phenytoin levels. Finally, inducers of CYP2C19 such as carbamazepine and rifampin may lower serum phenytoin concentrations [9].

Phenytoin is metabolized further by means of glucuronidation, then secreted in the bile, reabsorbed, and subsequently excreted in the urine as the glucuronide conjugate. The metabolism of phenytoin is highly dose dependent at low concentrations. At plasma concentrations less than 10 $\mu\text{g/mL}$ (40 $\mu\text{mol/L}$), its elimination is first order, with a constant percentage of drug being metabolized per unit of time. At higher concentrations, including concentrations in the therapeutic range (10–20 $\mu\text{g/mL}$ [40–80 $\mu\text{mol/L}$]), its metabolism becomes saturated, however, and elimination changes to zero order (i.e., a fixed amount of drug metabolized per unit of time) (Fig. 2). This change in kinetics can markedly prolong the elimination rate of phenytoin, which has an apparent half-life during therapeutic use of 6–24 h. When used therapeutically at the high therapeutic range, a modest increase in the daily dose may result in a disproportionate increase in the plasma concentration and subsequent toxicity. Individual variation occurs with regard to the serum or plasma concentration at which this transformation from first-order to zero-order kinetics occurs. Incremental increases in dose should be limited to the lowest increase possible, and patients should be monitored carefully, particularly when it is necessary to increase phenytoin doses to greater than 300 mg/day (or approximately 5 mg/kg/day) [8].

Fig. 2 The relationship between the dose and steady-state plasma concentration of phenytoin is illustrated for two patients. In both patients, there is a linear relationship between the dose and the plasma concentration at low doses. As the dose increases, there is a transition to a nonlinear relationship. This transition occurs at different doses in each patient (From Ref. [10])

Pathophysiology

The precise mechanism by which phenytoin exerts its anticonvulsant action is unknown. The two presumed mechanisms of phenytoin's anticonvulsant effect are prolongation of neuronal sodium channel inactivation (Fig. 3) and the resulting inhibition of excitatory neurotransmitter release (see ► Chap. 20, "Toxicant-Induced Seizures").

High frequency of neuronal action potential generation is responsible for seizure development. Suppression of this high-frequency firing may occur as a result of voltage-dependent sodium channel inactivation or prolongation of the recovery from inactivation. Phenytoin inhibits sodium channels by reducing their capacity for recovery from inactivation. Phenytoin stabilizes sodium channels in an inactive state and limits the ability of neurons to depolarize at high frequency [9]. Phenytoin does not affect low-frequency neuronal firing. At higher concentrations in vivo, phenytoin delays activation of outward potassium currents in neurons and prolongs the neuronal refractory period [11].

Fig. 3 Action of phenytoin

on sodium channel. (a) Resting state in which sodium channel activation gate (*A*) is closed. (b) Arrival of an action potential causes depolarization and opening of activation gate (*A*), and Na^+ flows into the cell. (c), When depolarization continues, an activation gate (*B*) moves into the channel. Phenytoin prolongs the inactivated state of the sodium channel, presumably by preventing reopening of the inactivation gate (*B*). (From Ref. [10])

Phenytoin also may exert some anticonvulsant effect by acting through adenosine receptors. Adenosine is an endogenous anticonvulsant that suppresses seizure propagation [12, 13] by inhibiting excitatory neurotransmitter (e.g., glutamate) release. Phenytoin may inhibit adenosine reuptake, resulting in a net increase in extracellular synaptic adenosine and enhancement of its effect on neurotransmitter release [13, 14]. Phenytoin has no clinically significant action at γ -aminobutyric acid receptors or known effects on calcium channel conductance.

At toxic levels in the brain, phenytoin suppresses memory and balance by inhibiting the only areas of the brain that exhibit spontaneous neuronal burst

discharge: the hippocampus and the cerebellum. Cerebellar stimulation and alteration in dopaminergic and serotonergic activity may be responsible for the acute dystonias and movement disorders such as opisthotonos and choreoathetosis that infrequently accompany phenytoin toxicity. Seizures after toxic phenytoin ingestion are extremely rare, and their mechanism is not understood [12–15].

Phenytoin also may inhibit myocardial sodium channels; however, cardiac disturbances and negative inotropy attributed to this effect of phenytoin are reported infrequently. Similar to other class 1B antidysrhythmics, such as lidocaine, phenytoin blocks cardiac sodium channels and has a minimal effect on potassium efflux. At therapeutic doses, no

effects are noted on electrocardiogram, and at toxic doses, the effects are typically insignificant [16–18].

Diluent Effects

The acute-onset cardiovascular toxicity seen with intravenously administered phenytoin has been attributed to its diluent. Older parenteral formulations of phenytoin contain 40% propylene glycol and 10% ethanol, adjusted to a pH of 12 with sodium hydroxide. The propylene glycol component seems to be responsible for the reported coma, seizures, circulatory collapse, and ventricular dysrhythmias [14] after rapid intravenous administration of phenytoin. Propylene glycol is a strong myocardial depressant with vasodilatory and vagal effects [16, 17]. In animals, phenytoin partially reverses the toxic effects that occur when propylene glycol is given alone [18]. Noncardiovascular effects of propylene glycol include hyperosmolality, hemolysis, and lactic acidosis [16]. In addition, the ethanol diluent fraction of phenytoin may precipitate a reaction in patients ingesting disulfiram or disulfiram-like medications.

Clinical Presentation

The clinical toxicity of phenytoin varies as a function of dose, duration, route, and rate of administration. The latter two parameters are paramount. The rapid intravenous administration of phenytoin carries the greatest risk of life-threatening toxicity occurring as a result of the propylene glycol diluent. The gravest consequences occurring after intravenous administration of phenytoin are cardiovascular (bradycardia, hypotension, and asystole) [19–21]. Toxicity from acute or chronic oral overdose may be manifested by nystagmus, nausea and vomiting, ataxia, dysarthria, choreoathetosis, opisthotonos, and central nervous system depression or excitation [22]. Deaths associated with oral ingestion of phenytoin are extremely rare and typically involve a coingestion [22, 23]. Major cardiac toxicity after oral overdose has never been reported [22, 23]. Tissue necrosis

and sloughing after extravasation of intravenous phenytoin also have been described [20, 22, 23].

Relationship Between Plasma Concentration and Toxicity

Therapeutic plasma phenytoin concentrations are 10–20 µg/mL (20–40 µmol/L), with a free phenytoin concentration of 1–2 µg/mL (2–4 µmol/L). Some patients require plasma concentrations greater than 20 µg/mL (40 µmol/L) for adequate seizure control [24]. The therapeutic range for phenytoin is narrow, and some patients have a greater predisposition for toxicity than others. Individual variation in toxicity is a function of baseline neurologic status, individual response to the drug, and free drug fraction. Patients with underlying brain disease are predisposed to toxicity and may become toxic at lower plasma concentrations [25]. In general, toxicity correlates with increasing plasma concentration, but this is not a universal tenet. Some patients tolerate concentrations greater than 40 µg/mL (80 µmol/L) [25]. Nystagmus typically appears first at phenytoin concentrations equal to or greater than 20 µg/mL (40 µmol/L) but may occur at lower or higher levels. Almost all patients with phenytoin-induced seizures have concentrations greater than 30 µg/mL (60 µmol/L). Signs of toxicity typically occur at free phenytoin concentrations equal to or greater than 2 µg/mL (4 µmol/L) and are consistently severe at greater than 5 µg/mL (10 µmol/L) [26, 27].

Central Nervous System Toxicity

Central nervous system toxicity after acute or chronic phenytoin overdose is manifested by nystagmus, dysequilibrium, and cerebellar ataxia. Central nervous system depression and cognitive defects (confusion, dizziness, and memory impairment) may occur [24, 25]. Paradoxically, high concentrations of phenytoin have been reported to be associated with seizures [24–27].

When phenytoin concentrations in the brain increase beyond therapeutic values, inhibitory cortical and excitatory cerebellar/vestibular effects

occur. The usual initial sign of toxicity is nystagmus, which is seen first on forced lateral gaze and subsequently becomes spontaneous. A decreased level of consciousness is common with initial sedation, lethargy, ataxic gait, and dysarthria. Progression to confusion, coma, and apnea can occur in massive ingestions [28]. Acute dystonias and movement disorders such as opisthotonos and choreoathetosis have been described [29]. Depressed or hyperactive deep tendon reflexes, clonus, and extensor toe responses also may be elicited [29–31]. Phenytoin-induced seizures are rare, universally preceded by other signs of toxicity, and usually brief and generalized [32, 33]. Some signs of neurologic toxicity may outlast the presence of measurable drug levels by weeks, especially mild peripheral neuropathy or acute, typically reversible cerebellar ataxia [34].

Vertical, bidirectional, or alternating nystagmus may occur with severe intoxication or be absent at levels high enough to cause coma, complete ophthalmoplegia, and loss of corneal reflexes. Absence of nystagmus does not exclude severe phenytoin toxicity. Nystagmus often returns as serum phenytoin concentrations decrease and coma lightens [26, 27, 35].

Cardiovascular Toxicity

Cardiac toxicity after oral phenytoin overdose in an otherwise healthy patient has not been reported and if observed warrants aggressive assessment for other etiologies. Acute cardiovascular toxicity has been limited almost entirely to cases involving intravenous administration at rates greater than 50 mg/min and is manifested by hypotension, decreased peripheral vascular resistance, bradycardia, conduction delays that may progress to complete atrioventricular nodal block, asystole, ventricular tachycardia, or ventricular fibrillation [16, 18].

Electrocardiographic changes reported are increased PR interval, widened QRS interval, and ST-T wave changes. Most of these effects can be attributed to rapid intravenous administration of the preparation containing propylene glycol and typically are avoidable with slower administration (50 µg/min of phenytoin or slower). In six healthy

volunteers taking approximately 1 g of phenytoin in a simulated oral overdose, sinus bradycardia and a shortened PR interval were noted in two patients but did not correlate with peak plasma phenytoin concentration [36].

Vascular and Soft Tissue Injury

Intramuscular injection of phenytoin may result in hematoma, sterile abscess, and myonecrosis [37] at the injection site. Reported complications after extravasation following intravenous infusion have included skin and soft tissue necrosis requiring skin grafting and compartment syndrome, gangrene and amputation. Rhabdomyolysis is a potential complication. A syndrome of delayed bluish discoloration of the affected extremity, followed by erythema, edema, vesicles, bullae, and local tissue ischemia, also has been described [38].

Non-Dose-Related Adverse Effects

Some adverse effects of long-term phenytoin administration are dose dependent and duration dependent, as noted earlier, whereas others seem to be non-dose related (i.e., idiosyncratic), such as gingival hypertrophy [34] and anticonvulsant hypersensitivity syndrome [32]. Hypersensitivity reactions to phenytoin usually occur within the first few months of therapy and include fever, skin rashes, blood dyscrasia, and hepatitis. Phenytoin, phenobarbital, carbamazepine, and perhaps felbamate all are causes of anticonvulsant hypersensitivity syndrome, which is related causally to the generation of toxic arene oxide metabolites in some individuals receiving these drugs. Treatment is generally supportive with removal of the offending agent and avoidance of other anticonvulsants that are metabolized to arene oxide compounds [29].

Diagnosis

Determination of a plasma phenytoin concentration is the most commonly used method of diagnosing dose-dependent toxicity. Use of this metric

is not infallible, however. The idiosyncratic phenytoin hypersensitivity syndrome is not dose dependent and is independent of the magnitude of the plasma concentrations. Patients with decreased plasma albumin concentrations generally have higher levels of free phenytoin (i.e., increased free fraction) and greater biologic effects. These patients may exhibit phenytoin toxicity despite total phenytoin levels in the usual therapeutic range. Patients who manifest toxic signs despite serum phenytoin concentrations in the therapeutic range, particularly if they may be hypoalbuminemic, should have free phenytoin concentrations measured, if available [36].

Toxicity from other anticonvulsants such as carbamazepine or phenobarbital, sedative-hypnotics, ethanol, or phencyclidine and nontoxicologic causes constitute the major differential diagnosis of a patient presenting with altered mental status, ataxia, and nystagmus. Most of these toxicologic diagnoses can be excluded by history and determination of drug concentrations.

Common Errors in the Assessment of Phenytoin Toxicity

Missing the diagnosis of phenytoin toxicity in hypoalbuminemic patients with normal blood phenytoin concentration

Failing to recognize that at toxic levels plasma phenytoin concentrations may decrease slowly owing to saturation of its metabolic enzymes

Not obtaining serial levels in an acutely toxic patient

charcoal administration. The administration of activated charcoal may reduce peak plasma phenytoin concentrations. Because virtually all patients with oral phenytoin toxicity as their sole acute medical diagnosis recover completely, it is unlikely that the administration of activated charcoal would alter their outcome. Whether activated charcoal administration shortens the clinical course of these patients is unknown (Level III). In addition, the presence of activated charcoal may prolong attaining stable therapeutic maintenance concentrations for seizure control.

Indications for ICU Admission in Phenytoin Poisoning

Significant coingestions

Coma

Cardiotoxicity from rapid administration

In human volunteer studies, multiple doses of oral activated charcoal decreases the area under the curve and phenytoin half-life [37, 38]. Multiple-dose activated charcoal is associated with possible aspiration in patients with depressed airway protective reflexes, however, and has never been of proven benefit in overdose patients [37, 38].

Because phenytoin is extensively protein bound, it is not appreciably removed by hemodialysis or hemoperfusion, and these two modalities are not useful in phenytoin toxicity. Seizures should be treated with intravenous benzodiazepines (e.g., diazepam) or barbiturates or both, and their occurrence should prompt a search for other causes, given the low likelihood of their causation by phenytoin.

Cardiovascular toxicity is unexpected after oral phenytoin overdose and should suggest other causes. Prolonged cardiac monitoring after oral ingestion is unnecessary. Hypotension that occurs during intravenous administration of phenytoin usually responds to discontinuation of the infusion and the administration of isotonic crystalloid. Atropine and temporary cardiac pacing may be used for symptomatic bradydysrhythmias.

Patients with serious complications after acute oral ingestion (e.g., seizures, coma, altered mental status, ataxia) should be admitted for further

Treatment

Supportive treatment is the cornerstone of medical management for phenytoin toxicity. Appropriate initial management of acute oral phenytoin overdose includes intravenous access; airway and ventilatory support as clinically warranted; and, if presentation is early (within the first hour) after ingestion, possibly oral or orogastric activated

evaluation and treatment. Others with only mild symptoms may be treated in the emergency department and discharged after their levels have returned to normal, provided that they are not actively suicidal and no coingestions warrant admission. Otherwise stable patients can be discharged even with supratherapeutic plasma phenytoin concentrations, provided that appropriate precautions against falling due to ataxia are taken (e.g., patient minimally ataxic, has caregiver at home, not anticoagulated).

Individuals with continuing signs and symptoms of phenytoin toxicity may need to be admitted or followed in an observation unit. Given the long and erratic absorption phase of phenytoin after oral overdose, the decision to discharge or clear a patient medically for psychiatric evaluation cannot be based on a single physical examination and serum concentration. Patients with signs or symptoms of chronic intoxication should be admitted for observation and discharged when the clinical effects have resolved, or minimized, and consecutive serum levels are decreasing. Phenytoin therapy should be stopped in all cases, and if toxicity continues to resolve, a serum level may be reassessed in 2–3 days to guide resumption of therapy.

Patients with significant or persistent complications after intravenous administration of phenytoin should be admitted and managed by appropriate supportive and diagnostic means. Orthopedic or plastic surgical consultation should be obtained for patients with significant extravasation of intravenous phenytoin or other signs of local vascular or tissue toxicity after infusion.

To prevent complications due to intravenous infusion of phenytoin, it should be administered under close observation, with constant cardiac and blood pressure monitoring. The infused solution should be given slowly (no faster than 50 mg/min if under direct physician observation and intensive cardiovascular monitoring or 25 mg/min under less closely monitored conditions) through a large, well-positioned catheter. Proportionately slower administration (e.g., 0.5–1 mg/kg/min up to adult infusion rates) should be given to pediatric patients.

Criteria for ICU Discharge in Phenytoin Poisoning

Decreasing plasma phenytoin concentrations
Absence of coma

Key Points in the Management of Phenytoin Poisoning

1. Supportive care usually is all that is needed.
2. Serial levels to establish a trend are commonly needed.
3. Rule out coingestions.
4. Give benzodiazepine for seizures, which are rare.

Fosphenytoin

The limiting properties of the parenteral form of phenytoin (incomplete aqueous solubility, toxic nature of the vehicle, and tendency to precipitate in intravenous solutions) have been addressed in the development fosphenytoin, a prodrug of phenytoin (Fig. 1). With a pH of 8, fosphenytoin is less irritating to the tissues than is phenytoin. Fosphenytoin is the disodium phosphate ester of phenytoin and is converted to phenytoin by phosphatases in the blood and various organs, principally liver. The concentration and dose of fosphenytoin are expressed in phenytoin equivalents. The conversion half-life is 10–15 min. Fosphenytoin is tolerated intravenously and intramuscularly, and most patients can be loaded successfully within 30 min without significant side effects [17–19]. Given intravenously, fosphenytoin can cause pruritus and, much less commonly than with intravenous phenytoin, hypotension. Blood pressure and cardiac monitoring are recommended when loading with fosphenytoin intravenously but not intramuscularly. With intravenous infusion pumps set at lower rates of phenytoin administration (e.g., <30 mg/min), however, adverse effects are not reported as commonly, suggesting a

continued role for the traditional form of the drug as a cost-effective alternative to fosphenytoin.

Bipolar disorder [5, 8]
Cocaine dependence [9] ^a

^aSeveral reviews have not found strong evidence supporting its use in the treatment of cocaine dependence [10]

Carbamazepine (CBZ) is a carbamylated derivative of iminostilbene and is related structurally to the cyclic antidepressants [1]. It is currently considered the drug of first choice for treatment of focal epilepsy [2, 3] and is also effective in the treatment of partial seizures (simple and complex) with and without secondary generalization, generalized tonic-clonic seizures (grand mal), and combinations of these seizure types [2]. Carbamazepine is also used to treat many other medical conditions (Table 1).

Due to its widespread use, the potential for CBZ poisoning is relatively high. Data from the American Association of Poison Control Centers documented 3964 cases of CBZ overdose in 2013, of which 11% had a moderate and 1.4% a major effect [11]. CBZ has also been reported as a substance of abuse [12, 13].

Biochemistry and Clinical Pharmacology

See Fig. 1.

Pharmacodynamics

The mechanism of action of CBZ is not fully understood. However, it inhibits activity of voltage-gated sodium channels and as a result stabilizes hyperexcited neurons, suppressing propagation of excitatory impulses [1]. It also inhibits presynaptic reuptake of adenosine, thereby enhancing presynaptic inhibitory modulation of excitatory neurotransmitters (e.g.:

glutamate) release. Glutamate activates the *N*-methyl-D-aspartate (NMDA) receptors allowing the influx of Na⁺ and Ca²⁺ into neuronal cells. A decrease in glutamate thus protects against seizures [1, 14].

It is hypothesized that an inhibitory effect on central dopaminergic and noradrenergic neurotransmission is responsible for the antimanic effects of CBZ [2].

Pharmacokinetics

Absorption of CBZ from the gastrointestinal tract is relatively slow yet bioavailability approaches 100% with the conventional tablet formulation. The controlled-release (CR) or extended-release (ER) formulations are absorbed more slowly and less completely than the immediate-release (IR), and bioavailability is about 15% lower for these formulations [1, 2].

When taken as a single oral therapeutic dose, the IR tablet commonly yields a peak concentration of unchanged CBZ within 4–12 h [1, 15]. When CR tablets are administered singly and repeatedly, peak concentration of the parent compound in plasma is 25% lower than with IR tablets. Liquid formulations are absorbed more rapidly [2].

Steady-state plasma concentration of CBZ is attained within about 3–4 days [15]. Controlled-release tablets result in a more stable plasma concentration and less fluctuation at steady state [2].

The apparent volume of distribution of CBZ is 0.8 to 1.9 L/kg [2]. Plasma protein binding is around 70–80% [15]. The concentration of unchanged drug in saliva and cerebrospinal fluid reflects the non-protein-bound fraction present in plasma and is approximately 20–30% of that in plasma [1, 2]. Carbamazepine is secreted in breast milk, with concentration ranging from 25% to 60% of plasma. Carbamazepine readily crosses the placenta [2, 16].

Carbamazepine is metabolized in the liver via the epoxide-diol pathway. The main metabolite (CBZ-10,11-epoxide [CBZE]) is pharmacologically active. Cytochrome P-450 3A4 is the major

Fig. 1 Carbamazepine is structurally similar to cyclic antidepressants

isoform responsible for this metabolism. A reactive arene oxide compound, distinct from the 10,11-epoxide metabolite, is also formed as a result of phase I oxidative metabolism of CBZ. This is thought to be the metabolite responsible for hypersensitivity reactions and teratogenic effects associated with CBZ administration [17]. Carbamazepine induces its own oxidative metabolism and that of other drugs. Given the gradual onset of this effect on drug clearance over the first few weeks of administration, it is considered the prototypical drug with time-dependent kinetics [2, 15].

The elimination half-life of unchanged CBZ after a single oral dose averages 36 h. After repeated administration, however, this varies from 16 to 24 h, depending on the duration of treatment. After a single 400-mg dose, around 72% is excreted in the urine mainly in the form of epoxide, hydroxylated, and conjugated metabolites. About 28% of a dose is also excreted in the feces [2, 15]. In patients receiving concomitant treatment with other cytochrome P-450 enzyme-inducing drugs, half-life values averaging 9–10 h may occur. Clinically important pharmacokinetic interactions with other drugs that may affect the plasma concentration of CBZ are listed in Table 2 [15, 18, 19].

Toxicokinetics

The clinical manifestations of toxicity develop within 1–3 h of overdose and usually involve the central nervous, cardiovascular, and respiratory systems. These clinical effects may be prolonged or delayed in onset, depending on the form and amount of CBZ ingested. These effects are due to both delayed and prolonged absorption and the production of the active metabolite, CBZ-10,11-

Table 2 Examples of pharmacokinetic drug-drug interactions with carbamazepine

Mechanism	Effect	Drug causes
CYP3A4 inhibition	Reduced clearance/ increased plasma concentration	Propoxyphene, fluconazole, itraconazole, ketoconazole, isoniazid, erythromycin, clarithromycin, cimetidine, verapamil, diltiazem, fluoxetine, fluvoxamine, nefazodone, ritonavir, grapefruit juice
CYP3A4 induction	Increased clearance/ reduced plasma concentration	Phenytoin, phenobarbital, valproate, rifampin

epoxide. Carbamazepine overdose results in slow and erratic absorption, and serum concentration may be persistently high for 2–3 days due to the continued absorption of CBZ from the gut. This results from the slow dissolution of CBZ from the tablet formulation and its anticholinergic effects on gut motility. Peak serum concentration can be delayed up to 96 h postingestion of CR preparations [20]. Elimination half-life in overdose ranges from 10 to 29 h [21].

Carbamazepine's active metabolite CBZE has roughly the same anticonvulsant effect as CBZ and also has neurotoxic effects. The ratio of CBZE to CBZ parent drug is concentration-dependent. When CBZ concentration is in the supratherapeutic range, CBZE concentration is

often greater than 150% of the CBZ parent drug concentration. When the CBZ concentration is within therapeutic range, the epoxide concentration tends to be lower and around 20% of the parent compound. This may explain the wide range of clinical effects seen when trying to correlate toxicity with serum CBZ concentrations [22].

At therapeutic concentrations, CBZ is 80% and CBZE is 50% protein-bound. However, both compounds exhibit concentration-dependent protein binding. At high serum concentrations, the fraction of unbound drug is much higher. The brain concentration of CBZ and CBZE is dependent on the free-drug concentration. As a result, in overdose, the concentration of both CBZ and CBZE in the central nervous system is relatively higher than at therapeutic doses [22].

Toxicodynamics

As well as its therapeutic effects on inactivated presynaptic sodium channels, CBZ is also a powerful antagonist at acetylcholine receptors (both muscarinic and nicotinic), NMDA, and central nervous system adenosine (A1) receptors. Many signs of toxicity are the result of effects on these receptors in overdose [1, 14].

Clinical Presentation of Carbamazepine Overdose and Life-Threatening Complications

Correlation Between Ingested Dose, Serum Drug Concentration, and Toxicity

Toxicity from CBZ overdose is dose-dependent. Ingestion of >20 mg/kg is often associated with an anticholinergic toxidrome and mild neurological symptoms and signs of mydriasis, nystagmus ataxia, and movement disorders. Severe toxicity is commonly seen after doses of more than 50 mg/kg with coma and seizures. Minor ECG changes may also occur commonly but rarely with significant arrhythmias [14, 23].

The degree of toxicity may relate to serum concentration. However, it is unclear whether

CBZ peak serum concentration correlates well with the severity of clinical effects. In a prospective study of 25 adult CBZ exposures, correlation between serious clinical signs and serum CBZ concentrations was poor [22]. However, in pediatric patients, peak serum CBZ concentration correlated well with the depth of coma, presence of convulsions, hypotension, and the requirement for mechanical ventilation [24]. A serum CBZ concentration of >25 mg/L correlates well with the presence of coma [25]. Significant toxicity (coma, seizures, respiratory failure and cardiac conduction defects) correlates with a serum concentration greater than 40 mg/L (170 μ mol/L) [26]. Toxicity may also be the result of high CBZ-epoxide concentration and a low CBZ-to-epoxide ratio [27]. This may occur at therapeutic doses, and the activity of unmeasured metabolite may provide an explanation for the limited correlation observed between serum CBZ concentration and clinical toxicity in some patients [22].

Anticholinergic Toxicity

An anticholinergic (AC) toxidrome is often prominent in the early stages of CBZ poisoning. Patients may show signs of significant delirium and agitation as well as peripheral signs of AC toxicity (tachycardia, ileus, urinary retention). This may precede the onset of coma. Anticholinergic effects on gut motility are also responsible for delayed and prolonged CBZ absorption and fluctuating signs of toxicity in some cases [14, 24].

Central Nervous System Toxicity

The most predominant neurologic signs are drowsiness, ataxia, nystagmus, and dystonia [24].

Coma

Coma with respiratory depression is reported in 21–48% of CBZ poisoning cases [22, 25]. CNS depression results from excess blockade of presynaptic voltage-gated sodium channels and the antagonistic effect on adenosine A1 receptors [14]. Massive ingestion of CBZ is associated

with deep coma, fixed dilated pupils, absent doll's eye reflex, and absent oculovestibular reflex. A full neurological recovery commonly results after several days. In one such case, the reported ingested dose was 5.8 g, and in another, peak serum CBZ concentration was 70 mg/L (295 μ mol/L) [28–30]. Cyclical coma, with waxing and waning of the patient's conscious state, is also reported after large CBZ ingestions. This is the result of fluctuating concentrations of CBZ/CBZE on the CNS and GI tracts. With high CBZ serum concentration, coma results and gut motility stops. As a result, absorption of further CBZ ceases. Already absorbed CBZ is metabolized in the liver, and as the serum concentration falls, conscious state improves and the anticholinergic effects on the gut also reduce. The result is an increase in absorption of CBZ from the intestine with consequent increase in serum concentration and recurrence of coma [14].

Seizures

The frequency of seizures after CBZ overdose increases as the Glasgow Coma Score falls [21]. Carbamazepine may cause seizures following overdose, particularly in patients with underlying seizure disorders [21]. Seizures occurring after overdose are the result of central anticholinergic antagonism of inhibitory presynaptic nicotinic receptors. This interrupts the normal control mechanism for release of neurotransmitters into the synapse. Antagonism of central A1-adenosine receptors, which have a role in decreasing excitatory neurotransmitter release, also plays a role in seizure propagation in overdose [14].

The concentration of the epoxide metabolite may also have a causative role in CBZ-induced seizures [31]. Seizure activity may be facilitated by hyponatremia from the antidiuretic actions of the drug [32]. Status epilepticus, although uncommon, has been described after CBZ overdose [25, 33].

Abnormal Movements

Abnormal movements, including choreoathetosis, dyskinesia, and dystonia, are described in patients taking CBZ therapeutically and in overdose. These may be related to its central anticholinergic effects [34, 35].

Cardiovascular Toxicity

Cardiovascular effects of CBZ poisoning are most likely to be the result of a combination of its anticholinergic and sodium channel blocking effects [14]. Carbamazepine is structurally similar to tricyclic antidepressants. This may influence its effects on myocardial sodium channel conductance. However, significant sodium channel blockade is uncommon following CBZ poisoning [1]. Heart block and bradycardia have been documented following exposure to CBZ, even at therapeutic concentrations [36].

In a retrospective case series of 62 patients with CBZ poisoning, 37% had sinus tachycardia, 24% transient right bundle branch block-like pattern, and 0.3% an atrio-ventricular block, which resolved in 48 h. Sodium channel blockade was not seen on any ECGs in this series [24]. However, isolated cases of QRS widening associated with CBZ poisoning are reported [37, 38].

Hypotension and poor myocardial contractility can result after significant CBZ intoxication. In a pediatric case series, cardiovascular instability resulting from reduced cardiac output and poor myocardial contractility was associated with a mean peak serum CBZ concentration of 50.4 μ g/mL (213 μ mol/L) [24].

Respiratory System Toxicity

Given the profound central nervous system depressant effects of CBZ, hypoventilatory respiratory failure and aspiration pneumonitis are anticipated adverse effects of acute overdose without appropriate and timely airway support. In addition, acute pulmonary edema is a potential complication of aggressive fluid volume replacement in the patient with CBZ-induced myocardial dysfunction [39].

Other Organ System Manifestations

Rhabdomyolysis and acute tubular nephropathy with myoglobinuria may occur after CBZ overdose, particularly in patients presenting after prolonged unconsciousness or generalized seizure activity.

Special Populations

Children

The endogenous elimination of CBZ is more rapid in children. However, incidence of dystonic reactions, choreoathetosis, and seizures may be higher in pediatric patients with overdose [40].

Pregnant Patients

Teratogenicity occurs at a rate of 9.7% with the use of any anticonvulsant medication [41]. Fetal abnormalities induced by aromatic anticonvulsants are most likely due to a fetal deficiency of the epoxide hydrolase enzyme necessary to break down the arene oxide [42]. Carbamazepine as a monotherapy during pregnancy has been associated with the increase risk of fetal malformations especially spina bifida [43].

Adverse Effects of Long-Term Carbamazepine Administration

Anticonvulsant Hypersensitivity Syndrome

Anticonvulsant hypersensitivity syndrome is an uncommon but potentially fatal multisystem disorder that occurs after exposure to CBZ, phenytoin, and phenobarbital [17, 44]. It may be related to the benzene ring structure of these drugs and the oxidative metabolism to a toxic arene oxide metabolite. The first reported case of CBZ sensitivity was described in 1965. The hypersensitivity reaction involves all organ systems, including the lung, liver, kidney, skin, and bone marrow [45].

There may be a pharmacogenetic component to the development of these reactions and an association between HLA allele variations and adverse reactions to some anticonvulsants. HLA-B15:02 is associated with carbamazepine-induced Stevens Johnson syndrome in Asian populations [46].

Sudden Unexplained Death in Epilepsy

The phenomenon of sudden unexplained death in epilepsy (SUDEP) is well described. There are many proposed mechanisms and associated risk factors. Two case-controlled studies have found an association between increased risk of SUDEP and therapeutic CBZ use. SUDEP cases had higher serum CBZ concentrations than those of matched controls. However, patients with recurrent seizures often require higher doses of anticonvulsants [47, 48].

Other Effects

Other adverse effects of CBZ therapy include inappropriate antidiuretic hormone secretion and hepatic and hematologic toxicity. Aplastic anemia has occurred uncommonly in association with CBZ therapy (1 in 200,000 patients treated). However, transient leukopenia, in 10%, and hepatic enzyme elevation, in up to 10%, are more common. These are more likely to occur in the first few months of treatment [2].

Diagnosis

In addition to the investigations required for the general care and management of the poisoned patient, serial quantitative serum analysis of CBZ concentration will assist in risk assessment and guide treatment. The accepted steady-state therapeutic concentration range for CBZ is 4–12 µg/mL (20–50 µmol/L) [1, 2, 15].

Treatment

Resuscitation and Supportive Care

Given the progressive clinical effects of CBZ toxicity, patients should to be closely monitored for clinical deterioration. Significant toxicity may be delayed due to erratic drug absorption, anticholinergic slowing of GI motility, or ingestion of controlled-release formulations [20, 21].

Endotracheal intubation and mechanical ventilation are indicated based upon standard clinical criteria such as in difficult to control agitation in patients exhibiting early anticholinergic toxicity or falling level of consciousness. Fluid volume resuscitation for hypotension should be undertaken with caution in CBZ-poisoning as patients are commonly euvoletic. Aggressive fluid resuscitation may result in pulmonary edema. An echocardiogram may assist in diagnosis of myocardial depression and guide pressor or inotrope use. Significant QRS interval prolongation is uncommon. However, as in the treatment of other sodium channel blocker overdoses, intravenous hypertonic sodium bicarbonate therapy should be administered to produce a systemic alkalemia if significant QRS-prolongation is present. Recurrent CBZ-induced seizures should be treated with γ -aminobutyric acid (GABA)_A agonists such as benzodiazepines (e.g., diazepam, lorazepam) and barbiturates (e.g., phenobarbital). (Grade III recommendation) In the presence of hypotension, cardiac failure or severe arrhythmia related to membrane stabilizing activity that is refractory to standard supportive care, veno-arterial extracorporeal cardiac assist devices could be used if available [49].

Activated Charcoal

A single dose of activated charcoal should be administered to patients ingesting more than 50 mg/kg as this dose is commonly associated with the development of significant toxicity (Grade III recommendation). Patients already exhibiting signs of CNS depression or agitation should be intubated first. Multiple-dose activated charcoal (MDAC) enhances CBZ clearance [34, 50]. Notably, it is unclear whether single or multiple doses of activated charcoal significantly improve clinical outcome [51]. However, in a study of 12 patients, receiving either single or multiple doses of activated charcoal, mean serum CBZ half-life was significantly shorter with MDAC (12 vs. 28 h). Mean duration of coma (20 vs. 29 h), and need for mechanical ventilation (24 vs. 36 h) were also shorter with MDAC administration [50].

Repeated administration of activated charcoal may be associated with significant risk, particularly from slowed motility and ileus from anticholinergic effects on the GI tract. Pulmonary aspiration of charcoal, bowel obstruction or ischemia and fluid, electrolyte, and acid-base abnormalities (when mixed with cathartics) have been reported [52]. Close observation of the abdomen for absence of bowel sounds, developing distension, or increasing nasogastric aspirates should alert the clinician that further charcoal administration is contraindicated.

Whole Bowel Irrigation

Whole-bowel irrigation has not been shown to change outcome in patients poisoned with controlled-release preparations of CBZ [51]. As with repeat-doses of activated charcoal, the development of ileus will contraindicate this therapy and may result in a significant risk of adverse events.

Extracorporeal Removal of Carbamazepine

Modern dialysis filters and machines with high blood flow rates have demonstrated comparable clearance when compared to older literature describing treatment with charcoal hemoperfusion [53, 54]. Extracorporeal CBZ removal is also superior to MDAC in enhancing CBZ elimination [55]. However, there are no studies comparing outcome after extracorporeal removal of CBZ to supportive care alone. Because of its low protein binding, the CBZ-epoxide metabolite is also dialyzable.

Intermittent hemodialysis and hemoperfusion both improve the features of severe CBZ poisoning. (Grade III evidence) Hemodialysis improves heart rate and level of consciousness and reduces convulsions as carbamazepine concentration falls after poisoning [56]. However, continuous renal replacement therapy and peritoneal dialysis are likely to be much less effective. The rate of improvement in clinical effects with these two therapies suggests little added benefit to supportive care alone [55].

Emergent intermittent hemodialysis is indicated in cases with refractory seizures and/or hypotension, or arrhythmias. (Grade III

recommendation) Dialysis may also benefit cases with prolonged coma or with rising or persistently elevated CBZ concentration greater than 60 mg/L (254 micromol/L) despite MDAC treatment.

Oxcarbazepine

Oxcarbazepine is a 10-keto analog of carbamazepine and has a very similar structure. As a result, very similar effects are expected with therapeutic use and in overdose. Oxcarbazepine is indicated in the treatment of partial and generalized tonic clonic seizures for adults and children as a mono or adjunctive therapy [2].

Pharmacodynamics

The pharmacological activity of oxcarbazepine is exerted through its active metabolite 10-monohydroxy derivative (MHD) which blocks voltage-gated sodium channels thereby stabilizing hyperexcited neurons.

Pharmacokinetics

Oxcarbazepine is a pro-drug that is rapidly absorbed and extensively metabolized in the liver to its pharmacologically active metabolite (10-monohydroxy carbamazepine, MHC). The apparent volume of distribution of MHC is around 0.5–1 L/kg and it is 40% plasma protein-bound. Oxcarbazepine has a very short elimination half-life of 1.3–2.3 h, whereas MHD's apparent half-life averages 9 h [2]. Therapeutic serum concentration for the MHC is 3–35 mg/L.

Overdose

There are limited data regarding effects of oxcarbazepine in overdose. In an observational poison center study, the most common clinical effects following overdose were drowsiness (25.3%), vomiting (8.4%), dizziness/vertigo (6.5%), tachycardia (3.2%), and agitation (1.8%). Major toxic effects, reported in 0.9%,

included coma, tachycardia, seizures, respiratory depression, agitation, confusion, and hypertension. However, both hypotension and bradycardia are reported following overdose [57].

There are a number of cases where large ingested doses were reported and only moderate adverse effects were observed. A 13-year-old boy, weighing 60 kg, ingested a reported total of 15,000 mg oxcarbazepine. The only abnormality observed was a GCS of 13, which gradually improved over 12 h. A single dose of activated charcoal was administered on presentation. Two hours after ingestion, his oxcarbazepine and MHC serum concentrations were 7.9 mg/L and 34.6 mg/L, respectively. Oxcarbazepine was quickly metabolized. Eight-hour serum concentration was 0.3 mg/L, becoming undetectable 24 h postingestion. MHD reached a peak of 46.6 mg/L, 8-h postingestion [58]. In another case, a 36-year-old man, weighing 78 kg, ingested a reported oxcarbazepine dose of 30,600 mg. On presentation, 2-h postingestion, vital signs and mental state were normal. Over the following 24 h, he was somnolent but always had a GCS of 15. Two hours postingestion, his serum oxcarbazepine and MHC concentrations were 31.6 and 37.2 mg/L, respectively. Again serum oxcarbazepine concentration fell rapidly to 0.67 mg/L at 24 h. MHD concentration peaked 7-h postingestion at 59 mg/L [59].

Oxcarbazepine is a pro-drug and the formation of the active MHD metabolite may be a rate-limiting process in the development of toxicity. This may contribute to the relatively low toxicity of the drug in patients with large ingested doses. However, the effect of interrupted enterohepatic recirculation/gut dialysis following charcoal administration cannot be excluded [58].

Adverse Effects of Oxcarbazepine in Therapeutic Dosing

Hyponatremia, from inappropriate secretion of antidiuretic hormone (SIADH) or an SIADH-like mechanism, is a common adverse effect of oxcarbazepine therapy. It is reported in up to 29.9% of patients using this agent. Approximately 2.5% of patients on oxcarbazepine may

have serum sodium concentrations of less than 125 mmol/L. However, symptomatic hyponatremia with nausea, headache, lethargy, and weakness is uncommon, but the risk may be greater in older patients. Hyponatremia resolves with fluid restriction and either a decrease in dose or cessation of the drug. Serum sodium monitoring should be performed in patients on long-term oxcarbazepine therapy [60, 61]. Other common reported side effects are dose-related and include drowsiness/somnolence, dizziness/vertigo, nausea/vomiting, diarrhea, and diplopia [62, 63].

Treatment

Resuscitation and Supportive Care

Supportive care management of oxcarbazepine poisoning is similar to carbamazepine poisoning [57].

Activated Charcoal

A single dose of activated charcoal reduced the absorption of oxcarbazepine in healthy volunteers, with repeated doses accelerating the elimination of its active metabolite MDC. This suggests that activated charcoal should be beneficial for gastrointestinal decontamination following oxcarbazepine overdose [64].

Extracorporeal Elimination

Limited data suggest that extracorporeal removal does not enhance oxcarbazepine or MHD elimination. In one study, the removal of MHD by plasmapheresis was only 3–4% of the daily therapeutic oxcarbazepine dose and 5–6% of the MHD body stores [65]. In a case of oxcarbazepine overdose, the clearance of MHD by dialysis was 30–100 times less than total endogenous clearance of the drug [66].

Key Points in the Evaluation and Treatment of Carbamazepine and Oxcarbazepine Poisoning

1. Carbamazepine is used widely in the management of a variety of neurobehavioral disorders, including trigeminal neuralgia, bipolar affective disorder, and epilepsy.

2. The major clinical manifestations of acute toxicity are coma, respiratory failure, seizures, anticholinergic toxicity, tachycardia, and hypotension.
3. Treatment of acute carbamazepine poisoning is largely supportive and may include airway and ventilatory support, intravenous pressor, or hypertonic sodium bicarbonate therapy, and seizure control with benzodiazepines and barbiturates.
4. Drug clearance of CBZ may be enhanced by multi-dose activated charcoal.
5. Extracorporeal treatments such as hemodialysis and hemoperfusion may enhance drug clearance in severe CBZ poisoning with hypotension or seizures refractory to supportive therapies or life-threatening arrhythmias. Intermittent hemodialysis is the preferred modality.
6. Carbamazepine is an established cause of anticonvulsant hypersensitivity syndrome and is associated with birth defects. Its use is contraindicated in the presence of a previous history of anticonvulsant hypersensitivity syndrome. Caution is also advised with regard to its use in pregnancy.
7. Oxcarbazepine is a pro-drug that is rapidly absorbed from the GI tract and requires hepatic metabolism to produce an active metabolite.
8. Poisoning primarily results in CNS depression.
9. Supportive care and respiratory support are the mainstay of therapy.
10. Activated charcoal may enhance oxcarbazepine clearance
11. Extracorporeal elimination does not appear to increase oxcarbazepine or MHD clearance.

The second generation anticonvulsants are generally considered to be the nonbenzodiazepine antiepileptic medications approved by the US Food and Drug Administration (FDA) after 1967 when valproic acid was marketed. There was a surge of newer anticonvulsant pharmaceuticals approved for clinical use, starting with vigabatrin in the late 1980s and continued throughout the 1990s (oxcarbazine, lamotrigine, gabapentin, felbamate, topiramate, tiagabine, fosphenytoin, levetiracetam, and zonisamide). Discontinuation of some of these pharmaceuticals in the USA and other countries has already occurred due to the decisions of the manufacturer, FDA, and other regulatory authorities, secondary to side effects and clinicians choosing more efficacious options. This chapter will not discuss all of the second generation anticonvulsants or the newest anticonvulsant lacosamide. Rather, it will focus specifically on gabapentin, lamotrigine, levetiracetam, and topiramate, because they are very common exposures or involve the greatest risk of toxicity resulting in the need for critical care management.

Gabapentin

In the USA gabapentin is approved therapy for partial seizures in children and adults and postherpetic neuralgia [1]. There are numerous off label uses including: neuropathic pain, mood disorders, posttraumatic stress disorder, bruxism, amyotrophic lateral sclerosis, trigeminal neuralgia, restless leg syndrome, parkinsonism, and reflex sympathetic dystrophy [1, 2]. However, the validity of the positive results found in the trials involving gabapentin in the treatment of neuropathic pain was discovered to be compromised by lack of research ethics [3].

Biochemistry and Clinical Pharmacology

Gabapentin was originally designed to act on postsynaptic gamma aminobutyric acid (GABA) channels, but its mechanism of action is not definitively known [1]. One suggestion for the

mechanism of action of gabapentin involves presynaptic voltage-gated calcium channels specifically possessing the alpha-2-delta-1 subunit [4]. These channels are thought to modulate release of neurotransmitters which participate in epileptogenesis and nociception.

Absorption of gabapentin occurs in the proximal small bowel and is saturable which may limit toxicity [5]. The volume of distribution is 58 ± 6 L, the protein binding is less than 3%, and has an elimination half-life of 5–7 h. Gabapentin does not undergo metabolism and is excreted in the urine as unchanged drug [2].

Pathophysiology of Toxic Effects

The toxic effects of clinically significant gabapentin overdose include lethargy, ataxia, central nervous system (CNS) depression, hypotension, bradycardia, tachycardia, and dizziness [1, 6].

The predominant clinical effect is CNS depression. Because gabapentin is excreted unchanged in the urine, patients with a history of end stage renal disease (ESRD) are particularly susceptible to more severe CNS depression. In a poison center case series, the clinical effects occurred less than 5 h with a median of 2 h and resolved in 24 h [1].

Clinical Presentation and Life-Threatening Complications

Two different poison center case series revealed a variable degree of clinical effects which included no symptoms to CNS depression, hypotension, and mechanical ventilation [1, 7]. It is difficult to determine a dose response from these studies.

The literature reports conflicting clinical effects after gabapentin overdose (Grade III). An old case report of a 49 g ingestion of gabapentin resulted in no serious consequences [8]. In contrast, a 62-year-old female was found dead in her hotel room with an elevated postmortem gabapentin serum concentration [9]. An accurate history, timing, and the dose she ingested are unknown.

A single intentional overdose in a patient with ESRD developed somnolence necessitating intubation [10]. Mental status returned to baseline quickly following hemodialysis. A 30-year-old female with ESRD, developed resting tremor and difficulty naming objects and performing three step commands after chronic cumulative gabapentin overdose [2]. She improved with a decrease in dose and regular HD. She was noted to have multiple comorbidities including lupus, previous stroke, and expressive aphasia that could have confounded the findings.

Diagnosis/Diagnostic Considerations

The diagnosis of gabapentin toxicity is based on history and clinical findings. A serum gabapentin level is not routinely available and should not be used to guide therapy. Diagnostic testing should be performed to assess end organ toxicity and coingestants.

Treatment

Gastrointestinal decontamination is theoretically attractive to prevent absorption of gabapentin, but the options have slowly decreased over time. Whole-bowel irrigation is not indicated for gabapentin overdose. Activated charcoal (AC) may absorb gabapentin, but its use must be strongly cautioned because of sedation and loss of airway reflexes, leading to increased risk of aspiration. The benefit may not outweigh the risk in many cases because of a low level of toxicity or the patient is so critically ill, decontamination will not help or could cause harm (Grade III recommendation.). There are no data indicating that the administration of activated charcoal alters the outcome in these patients. These same considerations apply to other second generation anticonvulsants.

There is no antidote for gabapentin overdose. The management involves supportive care, which includes cardiovascular monitoring, pulse oximetry, end tidal CO₂ monitoring, mechanical ventilation, sedation, and intravenous fluids and vasopressors for hypotension [7]. Elimination

may be enhanced with hemodialysis [10] (Grade III recommendation).

Special Populations

There are no studies specifically designed to investigate the effects in pediatric patients, although one poison center study included nine patients from 11 months to 18 years of age [1]. In three patients in which the dose was known to be 300 mg or less, no effect was seen. If it was unknown or 1,200 mg or greater, drowsiness, dizziness, ataxia, hypotension, and tachycardia were reported. The five hospitalized patients were treated with AC and cathartic, and the longest duration of clinical effects was 5 h or less. As in adults, diagnostics and treatment will be supportive and corrective of physiological abnormalities, until homeostasis is achieved (Grade III recommendation).

Data is limited but gabapentin does not appear to have increased risk to the fetus [11]. Treatment of the mother should be identical to the treatment of the nonpregnant patient. In general, gabapentin overdose is particularly ideal for a minimalist approach that places the mother and fetus at minimal risk (Grade III recommendation). Pregnant patients taking antiepileptics can register with the North American Antiepileptic Drug Pregnancy Registry, which can help inform them of possible malformations in the offspring.

In elderly patients with decreased renal function the therapeutic dose of gabapentin should be decreased. In the overdose patient, decreased renal elimination of gabapentin will increase the duration of clinical effects, but it is impossible to predict the duration of effects (Grade III).

Indications for ICU Admission

- Gabapentin with history of chronic kidney disease or end stage renal disease with a significant overdose
- CNS depression with concern about airway patency and respirations or cardiovascular insufficiency

Key Points

- Gabapentin overdose frequently produces mild symptoms.
- The parent drug is excreted unchanged in the urine.
- Clinically significant CNS depression is typically reserved for large overdoses or patients with end stage renal disease.
- Clinical effects are seen before 5 h and resolve within 24 h.

Criteria for ICU Discharge

- Baseline mental and cardiovascular status

Pharmacokinetics

- Elimination half-life of 5–7 h
- Volume of distribution: 58 \pm 6 L
- Protein binding: < 3%
- Mechanism of clearance: excreted in urine as unchanged drug
- Active metabolites: none, undergoes no metabolism
- Methods to enhance elimination: hemodialysis

Common Errors in Management

- Not exercising an appropriate degree of caution with gabapentin overdose and renal insufficiency

Biochemistry and Clinical Pharmacology

The anticonvulsant mechanism of action of lamotrigine is similar to phenytoin and carbamazepine. It binds to inactive voltage-gated sodium channels, preventing the release of glutamine. Without the excitatory stimulation of glutamine, propagation of the neuronal depolarizations is interrupted, causing seizures to terminate [12, 14]. Another major anticonvulsant mechanism is the inhibition of presynaptic voltage-gated calcium channels [15]. Inhibition of these N and P-O calcium channels prevents the presynaptic release of the excitatory neurotransmitter glutamate, halting seizure activity. Lamotrigine also has weak inhibitory effect on the 5-HT₃ receptor and dihydrofolate reductase [16].

The absorption of lamotrigine is rapid and complete with a bioavailability of 98%. The volume of distribution is 0.9–1.3 L/kg and protein binding is approximately 55%. Peak plasma levels occur at 1–3 h with therapeutic dosing, and hepatic metabolism creates inactive glucuronidated metabolites. The elimination half-life is 24–37 h with 90% of metabolites excreted in the urine [12, 14].

Valproic acid can compete with lamotrigine for glucuronidation, which could inhibit its metabolism, potentially prolonging the elimination half-life and toxic effects [12]. Lamotrigine metabolism is not affected by the typical inducers such as phenobarbital, phenytoin, rifampin, carbamazepine, and St. John's Wort.

Pathophysiology of Toxic Effects

Lamotrigine loses its selectivity toward the neurological sodium channels in overdose and causes blockade of cardiac conduction sodium channels, which can be significant enough to cause complete heart block and death [17]. These are the same channels that can be altered because of genetic mutations seen in Brugada syndrome, Romano-Ward syndrome, sick sinus syndrome, and heart block [13]. Sodium and potassium channelopathies have been linked to idiopathic

Lamotrigine

In the USA, lamotrigine is an anticonvulsant medication approved to treat simple and complex partial seizures; generalized tonic-clonic seizures; particularly absence and atonic seizures; and seizures from Lennox-Gestaut syndrome. Lamotrigine is also approved for treatment of bipolar disorder with depression predominance, because it inhibits the reuptake of serotonin, norepinephrine, and dopamine [12, 13].

epilepsy and could be the cause of sudden cardiac death in epilepsy patients [18].

Despite therapeutic use as an anticonvulsant, lamotrigine overdose has caused seizures in patients with or without epilepsy [15, 19, 20]. One patient also had a widened QRS, so the authors presumed the underlying mechanism of toxicity was sodium channel blockade in the cardiac and nervous systems, similar to tricyclic antidepressants. The mechanism of status epilepticus after lamotrigine overdose proposed by a group of authors is lamotrigine induced downregulation of GABA-A receptors and upregulation of glutamate receptors [15].

Drug-related eosinophilia and systemic symptoms (DRESS) has been reported from therapeutic lamotrigine [21, 22]. This hypersensitivity reaction can cause multiorgan injury or even failure, requiring critical care management. People with anticonvulsant hypersensitivity syndrome (ASH) should also avoid lamotrigine because it may stimulate the same reaction [23]. The US lamotrigine label contains a black box warning for skin rash with concern for progression to Stevens-Johnson syndrome.

Other toxic effects include bone marrow suppression from antifolate activity, hepatic necrosis from overdose or therapeutic dose, pancreatitis, and on a lighter note giggling [21, 22, 24–27].

Clinical Presentation and Life-Threatening Complications

The three large case series of lamotrigine overdose differ in their findings. The older study found the majority of lamotrigine overdose cases to be benign, and only 3% with major outcomes and no fatalities [28]. This poison center study combined accidental pediatric exposures and intentional overdoses (Grade III).

The second study was a retrospective evaluation of bedside consults over 9 years [29]. They had nine patients with a single ingestion of lamotrigine. Of these, 3/9 had seizures, 4/9 had hypertension, 5/9 tachycardia, 2/9 with insignificant QRS widening, and 4/9 QT prolongation. None of these effects were considered life-threatening (Grade III).

The latest case series also looked at one poison centers experience with second generation anticonvulsants and ranked lamotrigine the highest in toxicity [7]. Regardless of the differences, the greatest immediate threats to life are the effects on the central nervous and cardiovascular systems (Grade III).

Multiple reports of altered mental status and status epilepticus requiring intubation follow lamotrigine overdose [14, 30]. Ataxia has also been reported after status epilepticus resolved and in the absence of seizures [31, 32]. Myoclonus and choreiform movements have also been described after overdose [15, 33]. Patients with massive ingestions of lamotrigine may present initially with only encephalopathy [34]. One review of intralipid emulsion therapy reported the successful reversal of agitation, nystagmus and myoclonus [35]. Similarly, ataxia, encephalopathy, and seizures have also been reported in multiple pediatric cases [14, 31, 36] (Grade III).

Case reports also include fatal hepatic necrosis attributed to lamotrigine at therapeutic doses and nonfatal hepatitis that resolved with discontinuation of the drug [21, 24, 37]. DRESS syndrome and pancreatitis have also been described with lamotrigine therapy [22, 27].

Dysrhythmias and cardiovascular collapse are well-documented severe effects from lamotrigine overdose [17, 38–41]. These authors have universally described ECG finding consistent with sodium channel blockade, which include prolonged QRS, R wave > 3 mm in AVR. Prolonged QT is sometimes seen related to additional inhibited conduction through the delayed potassium rectifier channels (Grade III).

Diagnosis

The diagnosis of lamotrigine toxicity is based on history and clinical findings. Serum lamotrigine concentrations >14 mg/L are potentially toxic although there is no clear correlation between serum concentration and drug toxicity [12]. Serum concentrations are almost never available in a timely fashion to assist in clinical decision-making.

Cardiopulmonary monitoring is critical, along with serial ECGs when a rhythm disturbance is suspected. Frequent neurological assessment will often be necessary for seizures, myoclonus, and worsening encephalopathy.

Laboratory testing for organ injury related to cardiovascular instability, DRESS, or anticonvulsant hypersensitivity syndrome (AHS) is necessary. Consultation with a burn surgeon or dermatologist may be necessary to assist in management of the dermatological injury of DRESS or AHS.

Treatment

Gastrointestinal decontamination considerations are similar to gabapentin as outlined above. The treatment of lamotrigine exposure starts with quality supportive care. Benzodiazepines are the mainstay of treatment of seizures and status epilepticus. Intravenous lipid emulsion (ILE) therapy has been used successfully as an antidote to reverse severe cardiovascular toxicity related to lamotrigine overdose [38–41]. All of these patients already received multiple therapies that were not effective, including intravenous boluses of sodium bicarbonate. They all have rapid temporal improvement in hemodynamics, but one died later from anoxic brain injury (Grade III).

Hemodialysis or hemoperfusion may be beneficial in enhancing the elimination of lamotrigine because of the moderate protein binding and volume of distribution. One review did not recommend hemodialysis because only 20% was removed in 6 h [23]. In a case report of a patient with QRS widening which progressed to complete heart block, hemodialysis was started 74 h postingestion, decreasing the elimination half-life initially [17]. Multiple sessions occurred with variable success at enhancing elimination. Ultimately, the patient died from pneumonia and disseminated intravascular coagulation, when family withdrew care (Grade III).

Patients who have DRESS or AHS should have lamotrigine discontinued. Do not use other medications that cause AHS such as phenytoin, phenobarbital, and carbamazepine. Supportive care of

organ injury includes care similar to a burn patient with loss of protective skin (Grade III).

Special Populations

Treatment of pediatric patients is identical to the adult. Benzodiazepines for seizures, intravenous fluids, and vasopressors. Intravenous lipid emulsion therapy may be for serious cardiovascular instability such as wide QRS tachydysrhythmias and hypotension. One review reported successful use of ILE in 13/14 pediatric cases to reverse toxicity of a variety of lipophilic pharmaceuticals [42] (Grade III).

Pregnant patients should be treated in the same manner as the nonpregnant patients. Survival of the mother without hypoperfusion or hypoxia will benefit the fetus. Lamotrigine does cross the placenta during pregnancy (Grade III). There have been conflicting reports of lamotrigine causing orofacial cleft birth defects but a large case-control study failed to find an increase in birth defects with lamotrigine therapy [43].

Elderly patients with decreased glucuronidation will have a prolonged elimination half-life of lamotrigine. Changes in renal function should not affect the elimination of lamotrigine (Grade III).

Indications for ICU Admission with Lamotrigine Toxicity

- Status epilepticus
- Coma
- Dysrhythmias with QRS or QT prolongation
- Hypotension
- Systemic reactions such as Steven-Johnson syndrome

Key Points Regarding Lamotrigine Toxicity

- Neurologic abnormalities are common in lamotrigine overdose.
- Status epilepticus may occur in overdose.

(continued)

- Cardiovascular instability may be refractory to standard therapy and ILE may be considered.
- Fatal hepatic necrosis with lamotrigine have been reported.
- Skin rashes may occur and may progress to Steven-Johnson syndrome or toxic epidermal necrolysis. DRESS and AHS have also been reported with therapeutic lamotrigine.

Criteria for ICU Discharge Following Lamotrigine Toxicity

- Resolution of seizures, myoclonus, agitation, and sedation
- Resolution of dysrhythmias and hypotension
- Stabilization of organ injury in the setting of AHS and DRESS

Pharmacokinetics of Lamotrigine

- Volume of distribution: 0.9–1.3 L/kg
- Protein binding: 55%
- Mechanism of clearance: Glucuronic acid conjugation
- Active metabolites: none
- Peak plasma concentrations 1–3 h
- Therapeutic dosing elimination half-life 24–37 h

Common Errors in Management of Lamotrigine Toxicity

- Lamotrigine can cause seizures despite it being an anticonvulsant.
- Failure to recognize lamotrigine as the cause of DRESS, AHS, hepatic necrosis, and pancreatitis.

Levetiracetam

Levetiracetam was first approved by the FDA in 1999 for adjunctive treatment of partial onset seizures in adults [44]. Since then, it has been

approved as add on therapy for myoclonus and generalized seizures in adults and children and promising efficacy for the treatment of status epilepticus [45–47].

Biochemistry and Clinical Pharmacology

Levetiracetam has an unknown mechanism of action but may involve inhibition of voltage-dependent N-type calcium channels; facilitation of GABA-ergic inhibitory transmission through displacement of negative modulators; reduction of delayed rectifier potassium current; and/or binding to synaptic proteins which modulate neurotransmitter release [45, 47, 48]. The gastrointestinal absorption is rapid and nearly complete (95% bioavailability) [44]. It is highly water soluble having protein binding <10%, with peak plasma concentration 1 h after oral dosing and elimination half-life of 7 h. Twenty-four percent of levetiracetam is hydrolyzed to nonactive metabolites in tissues. Because it is not metabolized in the cytochrome system of the liver, there are no metabolic drug interactions. Elimination half-life can be increased by 40% if renal function is impaired.

Pathophysiology of Toxic Effects

The primary toxic effect of an oral overdose of levetiracetam ranges from no effect to severe central nervous system depression requiring intubation [49–51]. The pathophysiology of the sedation is unclear (Grade III).

Clinical Presentation and Life-Threatening Complications

Case reports include multiple supratherapeutic doses that did not result in clinically significant side effects in two children. These children were dosed with ten times and four times the therapeutic dose for 1 week with no side effects [50] (Grade III).

There is a case report of a 38-year-old woman who intentionally ingested 30 g of levetiracetam

presenting to the emergency department 6 h later obtunded [49]. She was intubated and supported on mechanical ventilation but rapidly improved in 24 h and was extubated, without permanent effects. The authors attributed the prompt clinical improvement to the calculated elimination kinetics of a 5 h elimination half-life compared to 6 h seen in healthy volunteers. In overdose first order kinetics were maintained (Grade III).

In comparison, a case report of a 49-year-old male who intentionally ingested 11 g of levetiracetam along with ethanol arrived in the emergency department six and half hours postingestion asymptomatic [52]. He remained clinically stable throughout his hospital stay for the next 22 h in the medical intensive care unit (Grade III).

A polydrug intentional ingestion of cyclobenzaprine, lacosamide, and levetiracetam causing sodium channel blockade and mechanical ventilation for 24 h has been reported [53]. This patient required intravenous boluses of sodium bicarbonate, electrical cardioversion, advanced cardiac life support, and norepinephrine infusion. The serum levetiracetam concentration was in the therapeutic range. The authors attributed the cardiac effects to the combination of lacosamide and cyclobenzaprine, because they both slow conduction through fast sodium channels.

There are two independent 9 year poison center studies of levetiracetam exposures. The first study of 222 exposures revealed no deaths with one major outcome (0.5%) and three (1.4%) moderate outcomes. The vast majority (90%) having minor, minimal, or no effects [51]. These effects included mild CNS depression, vertigo, or ataxia. The median age was 14 years old and 87% were unintentional.

The second study recorded the effects of multiple newer anticonvulsants including levetiracetam. The authors ranked them all with a toxicity score. Levetiracetam exposures had the lowest toxicity of all newer anticonvulsants [7]. In both studies, the predominance of minimal effects seen in unintentional pediatric exposures, and even intentional exposures, is reassuring that good outcomes are expected in the majority of levetiracetam cases (Grade III).

Diagnosis

Levetiracetam levels may be obtained and therapeutic concentrations are from 10 to 40 mcg/mL. However, monitoring drug levels is likely of limited clinical value except in massive overdoses with significant symptoms (Grade III).

Treatment

Gastric decontamination considerations are similar to gabapentin outlined above (Grade III). There is no antidote for levetiracetam overdose. Supportive care, most notably monitoring for central nervous system depression requiring tracheal intubation and mechanical ventilation until the effects have resolved [49]. Improvement is expected within 24 h from time of ingestion. Therefore, minimizing sedation in the mechanically ventilated patient will expedite extubation and decrease the opportunity for complications. Conversely, the initially asymptomatic patients monitored for 24 h without effect can be considered medically cleared (Grade III).

Enhanced elimination of levetiracetam with hemodialysis is theoretically possible with highly water soluble, low protein binding pharmaceutical [23]. Hemodialysis can clear 50% of levetiracetam from the blood in 4 h. Hemodialysis may be relevant in the massive ingestion or a renal failure patient with profound coma and elevated serum levetiracetam concentration. However, most cases will improve so rapidly, hemodialysis will not be necessary (Grade III).

Special Populations

Unintentional pediatric exposures are expected to cause minimal symptoms [51]. Even intentional ingestions may have only mild central nervous system depression. Frequent neurological monitoring for worsening central nervous depression in the initially symptomatic patient for 24 h will be adequate (Grade III).

Levetiracetam does cross the placenta. There is limited data available for levetiracetam during pregnancy, but thus far it is not associated with any birth defects. In an observational study measuring levetiracetam concentrations in pregnant individuals there was one stillbirth at 36 weeks but it is unknown if this was related to levetiracetam [54]. In another study designed to measure levetiracetam levels in neonates there were no birth defects observed, indicating levetiracetam is safe in pregnancy [55]. The pregnant patient should be assessed and treated in an identical manner as the nonpregnant patient. The benefit of treating the mother outweighs the risk or threat to the fetus (Grade III).

Prolonged sedation may be seen in an elderly patient with impaired renal function. Levetiracetam is predominantly eliminated in the urine. There is no concern for drug interactions with hepatic impairment or polypharmacy (Grade III).

Indications for ICU Admission with Levetiracetam Toxicity

- Significant CNS depression, airway monitoring

Key Points Regarding Levetiracetam Toxicity

- Levetiracetam overdose typically produces mild clinical effects.
- Mechanical ventilation has been reported in one 30 g overdose.
- If the patient is sedated, expect improvement in 24 h.
- Renal failure could prolong elimination and sedation.

Criteria for ICU Discharge After Levetiracetam Toxicity

- Baseline mental status

Pharmacokinetics of Levetiracetam

- Highly water soluble

- Time to peak serum concentration 1 h
- Protein binding: <10%
- Enzymatic hydrolysis to inactive metabolites
- Mechanism of clearance: 66% excreted in urine as unchanged drug
- Elimination half-life 7 h

Common Errors in the Management of Levetiracetam Toxicity

- If a patient has sedation after levetiracetam overdose, they should be admitted to a monitored setting because mechanical ventilation has been necessary in rare massive ingestions.
- Impaired renal elimination may prolong elimination and increase risk for sedation.
- Cardiovascular effects are not expected from levetiracetam.
- A major effect or death from levetiracetam in unintentional pediatric exposures.

Topiramate

Topiramate is a newer anticonvulsant medication used for the treatment of partial seizures, Lennox-Gastaut syndrome, and for generalized tonic-clonic seizures. Off label uses include cluster headaches, essential tremor, binge eating disorder, acute mania, Tourette's syndrome, neuropathic pain, and bipolar disorder [56, 57].

Biochemistry and Clinical Pharmacology

The complete mechanism of action of topiramate is not fully elucidated because of actions at many receptors [58, 59] (Fig. 1).

Absorption is rapid (81–95% bioavailability) and release preparations are unaffected by food [48, 55, 58]. Extended release preparations are affected by a high fat meal which increases the

Fig. 1 Physiology of carbonic anhydrase (CA) (http://www.uky.edu/~mtp/Diuretic_Drugs.htm)

maximum concentration and shortens the time to maximum serum concentration to approximately 8 h. Protein binding 15–41% and inversely related to plasma concentrations.

Metabolism occurs in minor amounts (20%) in the liver via hydrolysis, hydroxylation, and glucuronidation to inactive metabolites, so it is primarily eliminated (70%) unchanged in the urine [59]. The elimination half-life is 20–30 h [55]. Topiramate inhibits CYP2C19 which can cause increased phenytoin concentrations when coadministered. It also decreases estrogen production of oral contraceptive pills and decreases digoxin serum concentrations. The typical inducing anticonvulsants, phenytoin, phenobarbital, and carbamazepine cause a 50% reduction in topiramate serum concentrations. Valproic acid will decrease the topiramate serum concentration, by 10–15% [55].

Pathophysiology of Toxic Effects

Seizures and other neurological effects have been consistently reported after topiramate overdose and even supratherapeutic dosing [56, 57, 60–62]. The mechanism of the pathophysiology of seizures after exposure to an anticonvulsant is unclear. A mouse study suggests early after exposure, topiramate has proconvulsant effects, but has anticonvulsant effects after more prolonged exposure, similar to an overdose and its therapeutic effect [63] (Grade III).

Clinical Presentation and Life-Threatening Complications

The central nervous system is the primary target of toxicity from topiramate in supratherapeutic and

acute or acute on chronic overdose. Reported effects in adults and children include somnolence, slurred speech, ataxia, hallucinations, coma, seizures, and status epilepticus or nonconvulsive status epilepticus [56, 59–62, 64–66]. Hypotension responsive to intravenous crystalloid has been reported as well [62] (Grade III).

Topiramate is structurally similar to the carbonic anhydrase inhibitor acetazolamide, causing a non-anion gap hyperchloremic metabolic acidosis [62] (Fig. 1). Unpredictably, patients have presented with a severe metabolic acidosis, with or without seizure activity [57, 62]. The metabolic abnormalities have been reported to persist after neurological improvement, 72 h from ingestion [56] (Grade III).

A year review of 567 calls to US poison centers for single topiramate exposures was 90% unintentional pediatric (age ≤ 4 years old) cases [28]. The most common finding was no symptoms (62%). The most common symptom was drowsiness (16%). Only one patient had acidosis recorded and there were no reports of seizures. The most serious effects were seen after intentional overdoses. One patient required mechanical ventilation for lethargy and another was reported to have bradycardia and conduction abnormality. There were no fatalities (Grade III).

Another poison center study of topiramate exposures older than 15, found 56 single topiramate cases over 9 years [7]. They could not statistically find a correlation between dose of topiramate reported and clinical outcomes. None of their patients had seizures, 25% had CNS depression, 11% had metabolic abnormalities or cardiac effects, but no patients were treated with vasopressors. Two patients required mechanical ventilation and four sedation or intravenous fluids. Overall less severe effects, but intentional and unintentional exposures are included together.

The only fatality connected to topiramate was a 44-year-old male found dead in his bed [67]. Cerebral and pulmonary edema were discovered on autopsy. A central blood concentration of

170 mg/L was found postmortem. Ethanol, phenobarbital, and methotrimeprazine were also detected but felt not to be the cause of death by the authors. Without an accurate account of the premorbid events and clinical effects it is difficult to definitively determine topiramate was the cause of death with other confounding sedatives present (Grade III).

Diagnosis

Serum topiramate concentrations can be measured, but some clinical facilities may be limited in this capacity. The reported normal range of serum concentration is 5–25 $\mu\text{g/mL}$ [68]. Serum concentrations are almost never available in a timely fashion to assist in clinical decision-making. EEG monitoring is indicated if nonconvulsive status epilepticus is suspected (Grade III).

Treatment

Considerations regarding gastrointestinal decontamination are similar to gabapentin outlined above (Grade III). There is no antidote for topiramate overdose. Seizures respond well to treatment with benzodiazepines, and if necessary intubation and mechanical ventilation [56, 59, 60, 62]. Mechanical ventilation may be required if lethargy or coma occurs (Grade III).

The metabolic acidosis has been treated with bicarbonate infusions [57]. This may not be necessary for a non-anion gap metabolic acidosis or if re-equilibration of the acid base balance occurs with crystalloid resuscitation. The goal of therapy with the bicarbonate infusion is to only maintain the serum pH within the normal range. It is not meant to enhance elimination (Grade III).

Hypotension can be treated in the usual fashion starting with intravenous crystalloids. If this fails, norepinephrine is theoretically the vasopressor of

choice because of its effects on cardiac contractility and peripheral vasoconstriction (Grade III).

Enhanced elimination of topiramate with hemodialysis is feasible due to its properties of low protein binding and small volume of distribution [55]. Hemodialysis would only be indicated if there was prolonged coma or seizures, hypotension, or metabolic acidosis [23] (Grade III).

Special Populations

Clearance of topiramate is higher in pediatric patients [55]. The clinical effects include more sedation and ataxia but also include seizures in supratherapeutic dosing and overdose [64–66]. Gastrointestinal decontamination has the most benefit early after the acute overdose. It is not warranted in an unintentional pediatric exposure due to low toxicity. The same supportive treatment used for adults should be used in pediatric patients. Hemodialysis is unlikely to be required.

Topiramate crosses the placenta and is considered teratogenic. Topiramate has a strong association with cleft palate in offspring of women taking topiramate in the first trimester [69].

The dose of topiramate may need to be decreased in the elderly because of increased mental impairment, ataxia, and slurred speech [17]. Because topiramate is primarily excreted renally, the dose will need to be adjusted by 50% if creatinine clearance decreases below 70 mL/min [55].

In therapeutic doses, topiramate may cause increased renal calculi, metabolic acidosis, acute glaucoma, weight loss, and hyperthermia [17].

Indications for ICU Admission with Topiramate Toxicity

- Coma
- Status epilepticus
- Hypotension
- Severe metabolic acidosis

Key Points Regarding Topiramate Toxicity

- Unintentional pediatric exposures will often cause only sedation.
- Intentional overdoses most often have sedation, but can also have seizures, status epilepticus, hypotension, and metabolic acidosis that require critical care.
- It is currently difficult to predict the clinical effect from the dose.
- Non-anion gap metabolic acidosis may occur due inhibition of carbonic anhydrase.

Criteria for ICU Discharge After Topiramate Toxicity

- Resolution of seizures
- Resolution of sedation
- Resolution of hypotension
- Resolution of metabolic acidosis

Pharmacokinetics of Topiramate

- Absorption T_{max} (1–4 h)
- Volume of distribution 0.6–1 L/kg
- Protein binding: 15–41% and is inversely related to plasma concentrations
- Mechanism of clearance: 70% is released as unchanged drug
- No active metabolites
- Elimination half-life: 20–30 h
- Hemodialysis can be used to enhance elimination

Common Errors in Management of Topiramate Toxicity

- Failure to recognize seizures or non-convulsive status epilepticus
- Failure to recognize topiramate can cause a hyperchloremic metabolic acidosis
- Renal failure may increase the duration of effect of topiramate
- Overly aggressive gastrointestinal decontamination is not necessary

Table 1 Key aspects of the clinical toxicology of second generation anticonvulsants

Anticonvulsant	CNS	CV	Enhanced elimination	Special property	Antidote
Gabapentin	++	–	HD	Enhanced toxicity in renal failure	None
Lamotrigine	+++ +	++ ++	HD	DRESS/AHS	Intralipid
Levetiracetam	+	–	HD	Enhanced toxicity in renal failure	None
Topiramate	+++	+	HD	Carbonic anhydrase inhibitor	None

Key

CNS = central nervous system

CV = cardiovascular system

“+” = degree of severity

“–” = no toxicity

HD = hemodialysis

DRESS = drug rash with eosinophilia systemic symptoms

AHS = anticonvulsant hypersensitivity syndrome

Table 2 Toxicokinetic and toxicodynamic interactions of second generation anticonvulsants

Drug	Increased toxicity	Decreased effectiveness
Gabapentin	Renal failure	
Lamotrigine	Concurrent valproic acid Elderly patient with decreased glucuronidation	
Levetiracetam	Renal failure	
Topiramate	Renal failure	Concurrent phenytoin, phenobarbital, carbamazepine, and valproic acid

See Tables 1, 2, and 3.

Requests

Structures of each anticonvulsant for each section.

Picture of carbonic anhydrase inhibition in the kidney.

Table 3 Summary of other newer anticonvulsants

Felbamate
Therapeutic indications: partial seizures and Lennox-Gastaut syndrome
Indications for ICU admission
Altered mental status
Renal failure with significant electrolyte abnormalities
Hepatic failure
Key points
Mechanism of action unclear [70]
Symptoms following felbamate overdose symptoms include ataxia, slurred speech, nausea, and vomiting [70–72]
Crystalluria (with unchanged felbamate, monocarbamate felbamate, mercapturic acid conjugates of the metabolite 2-phenylpropenal) and acute renal failure have occurred, that did not require renal replacement therapy [71, 72]
Felbamate urolithiasis with chronic administration [73]
Aplastic anemia and hepatic failure have been reported [74,75]
Criteria for ICU discharge
Normal mental status
Resolution of significant renal, hepatic, and electrolyte abnormalities
Pharmacokinetics[70,71]
Structurally similar to meprobamate, which causes coma
Mechanism of action is unknown
90% renal elimination

(continued)

Table 3 (continued)

Felbamate
Felbamate is sparingly soluble in water
Common errors in management
Failure to recognize felbamate can cause acute renal injury or urolithiasis
Failure to recognize felbamate as a cause of aplastic anemia
Lacosamide
Therapeutic indications: adjunctive treatment for partial-onset seizures and diabetic neuropathy
Indications for ICU admission
Dysrhythmias, that may include atrioventricular blocks, PR interval lengthening, atrial fibrillation/atrial flutter [76, 77]
Depressed mental status requiring intubation
Key points
Lacosamide modulates voltage-dependent sodium channels [78]
Higher doses (600 mg/day) have resulted in dysrhythmias such as atrial flutter/atrial fibrillation [77]
Lacosamide modulates voltage-dependent sodium channels [76, 78]
Neurologic symptoms such as dizziness and headache may occur at therapeutic doses [79]
GI symptoms such as nausea, vomiting may occur at therapeutic doses [79]
Criteria for ICU discharge
Resolution of dysrhythmias
Resolution of altered mental status
Pharmacokinetics
Lacosamide is excreted unchanged in the urine and undergoes minimal hepatic metabolism
Common errors in management
Increased risk of drug side effects with patients with cardiac and renal disease may occur
Express caution when lacosamide is used concurrently with other drugs known to prolong the PR interval, such as carbamazepine [77]
Tiagabine
Therapeutic indications: adjunctive treatment of refractory partial seizures [80, 81]
Indications for ICU admission [80, 82, 83]
Agitated delirium
Status epilepticus
Coma
Key points [82–85]
Mechanism of action of Tiagabine with selective inhibition of neuronal and glial GABA uptake that results in increased GABA-mediated inhibition in the brain
Seizures may occur after overdose ranging from a single seizure to status epilepticus

(continued)

Table 3 (continued)

Felbamate
Nonconvulsive status may also occur
Criteria for ICU discharge
Resolution of seizures or status epilepticus
Normal mental status
Pharmacokinetics [81]
Tiagabine is rapidly absorbed after oral administration and undergoes extensive hepatic metabolism
Metabolites are excreted into the bile
Common errors in management
Failure to recognize convulsive or nonconvulsive status epilepticus
Zonisamide
Therapeutic indications: treatment of partial and generalized seizures
Indications for ICU admission [86]
Significant CNS depression, possibly requiring intubation
QRS widening
QT prolongation
Key points
Zonisamide acts on voltage-gated sodium and calcium channels and has a modulatory effect on GABA-mediated neuronal inhibition
Neurologic side effects predominate at therapeutic doses such as somnolence, dizziness, headache, and nausea [85]
Zonisamide has an inhibitory effect on carbonic anhydrase and may lead to nonanion gap metabolic acidosis [86]
One case report demonstrated mild QRS conduction delay to 102 ms
Spontaneously improved to 85 ms on hospital day 3 [86]
Zonisamide is amenable to hemodialysis, with one study indicating 50% reduction in zonisamide concentration following one 4.5 h hemodialysis session [87]
Criteria for ICU discharge
Baseline neurological status
No cardiac conduction abnormalities
Pharmacokinetics [86]
Rapidly and completely absorbed after oral administration
Hepatic metabolism with primarily urinary excretion
35% excreted as unchanged drug
Common errors in management
Failure to recognize cardiac conduction toxicity
Failure to recognize hemodialysis can enhance the elimination of zonisamide
Failure to recognize nonanion gap metabolic acidosis may be related to zonisamide

Pharmacokinetics of Valproic Acid

Volume of distribution:	0.22 L/kg
Protein binding:	93%
Mechanism of clearance:	0.0066 L/kg/h, liver
Plasma half-time (half-life):	Approximately 10 h
pKa:	4.60
Active metabolites:	Present, but in small concentrations
Methods to enhance clearance:	High-flux hemodialysis, multiple-dose Activated charcoal; may consider Hemoperfusion (evidence level II-3)

Valproic acid (VPA) was discovered by chance to have anticonvulsant activity when it was used as the vehicle for administration of other compounds that were being studied for antiepileptic activity. It now is used widely not only as an anticonvulsant but also in psychiatry as a mood stabilizer for patients with bipolar disorders. Valproic acid was approved for use in the United States in 1978 after more than 10 years of use in Europe. In recent years there have been advances in knowledge of the pathophysiology of VPA toxicology with potential implications for the management of poisoning and possible identification

of genetic risk factors. In 2013 in the United States, the poison center voluntary reporting data showed 2,923 single exposures, of which 1,136 were intentional; there were two deaths [1]. There are various dosage forms: intravenous, 100 mg/mL (Depacon[®]); oral VPA capsules USP, 250 mg (Depakene[®] and generics); VPA syrup, 250 mg/mL (Depakene[®] and generics); divalproex (a stable coordination compound of VPA and sodium valproate in a 1:1 molar ratio) (Depakote[®] sprinkle capsules, 125 mg; Depakote[®] delayed-release tablets, 125, 250, and 500 mg; Depakote[®] ER extended-release tablets).

Biochemistry and Clinical Pharmacology

Valproic acid (*n*-dipropylacetic acid) is a branched-chain carboxylic acid. Its chemical structure is shown in Fig. 1. VPA is metabolized in humans to multiple metabolites (Fig. 2). A major portion of a daily dose is conjugated and excreted as glucuronides in urine. Beta-oxidation results in metabolites 2-en-VPA (2-propyl-2-pentenooic acid) and 3-keto-VPA (2-propyl-3-keto-pentanoic acid); both are major human plasma metabolites [2]. Beta-oxidation metabolites are the major metabolites found in urine (about 70%); omega-oxidation and omega-1-oxidation metabolites (3-hydroxy, 4-hydroxy, 5-hydroxy, mostly as glucuronides) are found in lesser amounts in the urine (about 30%) [3]. The hepatotoxic metabolite, 4-en-VPA, results from cytochrome P450 enzyme activity. Studies with human liver microsomes (smooth endoplasmic reticulum) indicate that the cytochrome P-450

isozymes CYP2C9 and CYP2A6 are responsible for 4-en-VPA formation [4]. Additional in vitro studies with human hepatoblastoma cells show that the p-450 isozyme CYP2E1 is responsible for further metabolism of 4-en-VPA to a reactive metabolite [5]. A carbon-centered free radical at the C-4 position in the VPA molecule probably serves as at least one key intermediate [6]. The 3-en-VPA is formed reversibly from 2-en-VPA by isomerization. In plasma, 2-en-VPA (less toxic than VPA or 4-en-VPA) is one of the major circulating metabolites of VPA. Valproic acid therapy (assessed after 3 weeks) results in a small (1.5–2 times) autoinduction of its own metabolism by beta-oxidation but not glucuronidation or 4-hydroxylation [7].

Valproic acid is highly (85–95%), but not tightly, bound to serum albumin [8, 9]; this less tight binding (lower avidity) correlates with clinical reports of clinically significant effectiveness of extracorporeal elimination in poisoned patients [10, 11]. Human brain-to-plasma ratios of VPA range approximately from 0.07 to 0.28. It is thought that an active transport process, the monocarboxylic acid transporter, regulates VPA distribution between plasma and brain [2, 12].

Cerebrospinal fluid (CSF) concentrations of gammaaminobutyric acid (GABA), a major inhibitory neurotransmitter, are increased with VPA treatment, with values of approximately 120 pmol/mL in untreated children compared with approximately 250 pmol/mL in treated children [11]. Elevated serum and CSF glutamine concentrations may correlate better with clinical signs of VPA toxicity than do serum ammonia concentrations [13]. VPA enters human CSF relatively rapidly after dosing. The time to maximum

Fig. 2 Metabolism of valproic acid (VPA) in humans. *GABA* gamma-aminobutyric acid, *GAD* glutamic acid decarboxylase

human subdural CSF VPA concentration is 3.5–5.5 h (14.15). Recent studies have shown that VPA has neuroprotective actions that appear to be related to its inhibition of histone deacetylases [16–19].

Pathophysiology of Toxic Effect

The mechanism of anticonvulsant action of VPA seems to be elevation of brain GABA (see Fig. 2). Valproic acid-induced elevation of brain GABA in the substantia nigra is thought to be important because this area of the brain is involved in seizure control and propagation [14]. Laboratory animal data show that VPA increases the apoenzyme of glutamic acid decarboxylase, the enzyme that synthesizes GABA. Some laboratory animal data show that 2-en-VPA is more potent than VPA in potentiating brain GABA-mediated postsynaptic inhibitory responses [14]; 2-en-VPA may contribute significantly to the anticonvulsant effect of VPA in vivo. It is possible that the coma that characterizes VPA overdose also may be due to elevation in brain GABA and possibly 2-en-VPA's postsynaptic inhibitory effects. Other limited data suggest that clinical recovery correlates better with decline in elevated serum glutamine concentrations and EEG improvement rather than the decrease in elevated blood ammonia concentrations [13]. Ammonia is converted to urea and glutamine. Brain glutamine synthesis mostly occurs in astrocytes. In hyperammonemia, the excess glutamine is thought to impair astrocyte function. The osmotic gliopathy theory is that excess glutamine along with hyperammonemia result in osmotic stress which contributes to encephalopathy [15]. In view of this theory, future development of a glutamine synthetase inhibitor potentially may offer a beneficial treatment strategy.

Hepatotoxicity

Most fatalities from VPA poisoning are due to hepatotoxicity, although cerebral edema with deep coma, which may occur in acute toxicity or

as a consequence of hepatic encephalopathy, also poses a risk for death. Valproic acid hepatotoxicity may be dose dependent or idiosyncratic. Dose-dependent hepatotoxicity is more frequent, reproducible, and reversible, whereas idiosyncratic hepatotoxicity is unpredictable, is life threatening, has a long latent period, and is rare (estimated frequency <1 in 10,000). Risk estimates show 37 cases of the fulminant fatal form of VPA hepatotoxicity reported to the manufacturer for the 6-year period of 1978 through 1984. An estimated 400,000 patients were treated with this drug during this period. Of the 37 patients, 27 (73%) were between the ages of 5 months and 11 years. At highest risk for death were children 2 years of age or younger who were treated with multiple anticonvulsants and had significant disease in addition to seizures, such as congenital defects and mental retardation [16]. The fatality rate due to hepatotoxicity in these children was 1 in 500, whereas the fatality rate in the entire group was 1 in 10,000. Use of multiple anticonvulsant drugs in young children increased the fatality rate to 1 in 500 compared with 1 in 7,000 seen in children on monotherapy. Of the 37 patients with fatal hepatotoxicity, 17 also were receiving phenobarbital [14]. More recent reports further substantiate this epidemiological and risk factor data [17, 18]. Liver histology typically shows steatosis and necrosis. Liver ultrastructure findings include enlarged mitochondria with distorted matrix and fragmented cristae [19]. Three risk factors for VPA hepatotoxicity are young age, multiple antiepileptic drug therapy, and high VPA plasma concentrations [16]. An immediately preceding febrile illness is present in about half of children who develop VPA hepatotoxicity [20]. Decreased caloric intake often is associated with a febrile illness. This decreased intake results in increased levels of endogenous fatty acids, which may compete with VPA for beta-oxidation. It appears that the combination of factors of young age, polytherapy, status epilepticus, and febrile illness may result in mitochondrial dysfunction. Some epileptic children develop status epilepticus just before the onset of VPA hepatotoxicity [16] with implications for energy depletion in mitochondria.

The pathogenesis of VPA hepatotoxicity remains uncertain. Hypotheses for the biochemical basis of VPA hepatotoxicity include hyperammonemia, carnitine deficiency, preexisting inborn errors of metabolism, diminished free radical scavenger activity, and toxicity caused by unsaturated VPA metabolites. A polymorphism in a carbamoyl phosphate synthetase gene is reported to correlate with risk for hyperammonemia associated with VPA in whites but not in Japanese orientals [21, 22]. A polymorphism in superoxide dismutase is reported to correlate with an increased risk of elevation of liver serum aminotransferases and gamma-glutamyltransferase [23, 24].

L-Carnitine increases fatty acyl group transport into mitochondria (Fig. 2) and helps maintain the ratio of acyl to free coenzyme A (CoA). Patients receiving VPA therapy have an ongoing biochemical process that uses L-carnitine to maintain mitochondrial metabolism [19]. Mitochondrial metabolic stress induced by increased catabolism brought on by seizures or infection increases the risk of hepatic failure due to an insufficient reserve of L-carnitine, needed for mitochondrial metabolism, including VPA detoxification (see Fig. 2). One postulation is that L-carnitine supplementation may increase the beta-oxidation of VPA, thus decreasing cytosolic omega-oxidation and the production of toxic metabolites that are related to liver toxicity and ammonia accumulation.

The 4-en-VPA metabolite is thought to be at least in part mechanistically related to dose-dependent VPA hepatotoxicity. This metabolite, 4-en-VPA, has structural similarity to other known liver toxins, such as hypoglycin A (methylene cyclopropylacetic acid) and 4-pentenoic acid. These latter two compounds can produce microvesicular steatosis in the livers of laboratory animals, a characteristic feature of Reye's syndrome [25]. A large increase in VPA plasma concentration results in a large increase in 4-en-VPA. An extensive detailed study of VPA metabolism in cases of VPA hepatotoxicity concluded, however, that 4-en-VPA is not the decisive hepatotoxin [26]. In laboratory rats, 4-en-VPA is steatogenic but does not cause hepatocyte necrosis. In one study, younger patients had greater

formation of 4-en-VPA than older patients [20]. In another study, children younger than 2 years of age with VPA hepatotoxicity had lower plasma 4-en-VPA than children older than 2 years of age (whose age averaged 9.5 years) [26]. The ratio of human plasma 4-en-VPA to VPA increases as the total plasma VPA concentration increases. By contrast, the human plasma ratios of 2-en-VPA to VPA and 3-en-VPA to VPA decrease at high plasma concentrations of VPA. This decreased metabolic conversion of VPA to 2-en-VPA and 3-en-VPA at high plasma concentrations of VPA may be due to autoinhibition or saturation of mitochondrial beta-oxidation of VPA because VPA is an inhibitor of mitochondrial fatty acid beta-oxidation (see Fig. 2), with inhibition of 3-ketoacyl-CoA thiolase being most important. What follows is a limited capacity for mitochondrial beta-oxidation, which may become exhausted, leading to unknown metabolic reactions resulting in hepatotoxicity [27]. A 1.0 g oral dose or 400 mg intravenous dose of VPA administered to fasting human adults results in approximately a 75% decrease in plasma 3-hydroxybutyrate and an approximately 60% decrease in plasma total ketones, with increases of lactate, pyruvate, alanine, and glycerol [28]. Valproic acid decreases beta-oxidation of endogenous fatty acids. Clinically, VPA hepatotoxicity incidence is increased in patients who also are treated with other antiepileptic drugs, such as phenytoin, phenobarbital, and carbamazepine, which are known to induce cytochrome P-450. It is possible that cytochrome P-450 enzyme induction results in increased 4-en-VPA production from VPA and further metabolism of 4-en-VPA to a reactive intermediate metabolite. Patients treated with multiple P-450 enzyme-inducing antiepileptic drugs seem to have increased inhibition of beta-oxidation of VPA that may be due to reduced valproyl-CoA formation and greater depletion of carnitine [29, 30]. This altered VPA metabolic profile of production of 4-en-VPA and decreased beta-oxidation of VPA also is reported in patients with fatal VPA hepatic failure [31, 32]. Experimentally, VPA hepatotoxicity in laboratory rats can be predicted by the urinary excretion of total

4-ene-VPA (free plus glucuronide conjugate) [33]. Altered fatty acid metabolism occurs with VPA-induced hepatotoxicity; SREBP-1c (sterol regulatory element-binding protein 1c) and PPAR-alpha (peroxisome proliferator-activated receptor-alpha) are two transcription factors important in fatty acid synthesis and fatty acid degradation, respectively. VPA activates SREBP-1c resulting in increased mRNA expression of acetyl-CoA carboxylase 1, fatty acid synthase, and stearoyl-CoA desaturase 1; VPA inhibits PPAR-alpha resulting in decreased mRNA expression of 3-hydroxy-3-methylglutaryl-CoA synthase 2 and carnitine palmitoyltransferase 1A [34]. Thus, these biochemical actions may be a part of the mechanism of VPA hepatotoxicity. Coadministration of DHA (docohexaenoic acid, a polyunsaturated omega-3 fatty acid) with VPA decreases valproic acid hepatotoxicity in laboratory rats and increases VPA anticonvulsant action [35]. Additional studies of this interaction of potential therapeutic benefit are needed to determine possible clinical utility. Some human data suggest that cotreatment with both L-carnitine and pantothenic acid may offer increased protection against VPA hepatotoxicity compared to L-carnitine alone [36]. Laboratory rat studies show the potential of measuring selected substances to predict hepatotoxicity of valproic acid and other drugs in individual animals prior to the onset of clinical drug-induced liver injury (e.g., 8-hydroxy-2'-deoxyguanosine, octanoyl-carnitine, interleukin (IL)-1 beta, MCP-1/Ccl 2 (monocyte chemoattractant protein-1/CC-chemokine ligand Ccl 2) RNA, and others) [37–42].

Autoantibodies

Covalent plasma protein adducts of VPA and antibodies to these protein adducts are formed in humans (9 of 57 persons tested) but at low titers. This formation occurs because VPA acyl glucuronide nonenzymatically reacts with plasma proteins. Epileptic patients taking VPA chronically have measurable VPA plasma protein adducts at

concentrations of approximately 0.75 microgram VPA equivalents/mL [43].

Teratogenicity

Structure-activity studies in laboratory animals showed that other branched-chain carboxylic acid analogues also have anticonvulsant activity. Some of these do not have teratogenic activity, in contrast to VPA, which is a known human teratogen. VPA is associated with neural tube defects [44].

Clinical Presentation and Life-Threatening Complications

After an acute large overdose, drowsiness progressing to coma usually occurs relatively rapidly but may progress more gradually, particularly with the divalproate form. Metabolic acidosis, hypoglycemia, hypocalcemia, hypophosphatemia, and hypernatremia may become severe and potentially life threatening. Hyperammonemia and elevated serum liver enzymes may occur after either acute overdose or long-term chronic therapy [45, 46] and typically are not life threatening in most patients. Occasionally, severe life-threatening hepatotoxicity may occur, especially in patients on chronic therapy. Thrombocytopenia, occasionally requiring platelet transfusion, and leukopenia are potential risks. Delayed life-threatening cerebral edema appearing in a few to several days may occur in severely poisoned patients. In 133 VPA overdose patients with peak serum VPA concentrations averaging 380 mg/L (2,660 μ mol/L) and ranging from 110 to 1,840 mg/L (770–12,880 μ mol/L) (therapeutic range 50–100 mg/L [350–700 μ mol/L]), findings included lethargy in 94, coma in 19, tachycardia in 24, aspiration in 8, metabolic acidosis in 8, and hypotension in 4 [47]. Peak serum VPA concentrations greater than 850 mg/L (>5,950 μ mol/L) are more likely to be associated with coma; peak serum VPA concentrations

greater than 450 mg/L ($>3,150 \mu\text{mol/L}$) are more likely to be associated with moderate or major adverse outcome. Of 133 patients with transient thrombocytopenia 11 had peak serum VPA concentrations greater than 450 mg/L ($>3,150 \mu\text{mol/L}$) [47]. One of the highest reported serum VPA concentrations was 2,700 mg/L ($18,900 \mu\text{mol/L}$) in an adult patient with a fatal outcome [48].

Diagnosis

The diagnosis of VPA poisoning, similar to many drug poisonings, is helped enormously by an available and accurate history of ingestion. When a patient presents with an unknown ingestion and laboratory data are pending, differential diagnosis may be difficult. In this latter scenario, coma with or without metabolic acidosis may be present, and identification of VPA in urine or blood specimens may be required to support the diagnosis. This identification should be followed by quantitative plasma concentrations for confirmation. Plasma VPA concentrations greater than 100 mg/L ($700 \mu\text{mol/L}$) are of concern. Concentrations greater than 450 mg/L ($3,150 \mu\text{mol/L}$) and 850 mg/L ($5,950 \mu\text{mol/L}$) are of increasingly serious concern, although it is recognized that a close correlation between plasma VPA concentrations and clinical severity does not exist [47]. An initial level obtained shortly, 1–2 h, after overdose may be misleadingly low; therefore it is recommended to repeat a level to assess for delayed absorption.

Treatment

Treatment considerations include general supportive care, gastrointestinal decontamination with activated charcoal, selective high-flux hemodialysis, and also L-carnitine and N-acetylcysteine administration (evidence level II-2 and II-3). Some authors recommend the use of naloxone (evidence level III). All patients with VPA toxicity should be monitored closely for depression of mental status and need for airway protection.

Patients with an altered mental status should have their arterial ammonia blood concentration measured. Glucose should be monitored because of the possibility of hypoglycemia.

Gastrointestinal Decontamination

Activated charcoal given 5 min after an oral dose of 300 mg of VPA to six healthy human volunteers reduced absorption of VPA by 65% [49]. When multiple-dose activated charcoal was started 4 h after an oral dose of 300 mg of VPA (4–32 h after VPA, repeated doses of activated charcoal, total of 80 g, administered), there was no significant difference in the area-under-the-time-curve or plasma half-time (half-life) (20 h compared to 22 h) [50]. Single-dose activated charcoal given relatively soon after ingestion, but perhaps less likely multiple-dose activated, may be of benefit in patients with VPA overdoses (evidence level II-3). One patient with a fatal overdose of VPA had VPA concentrations in bile of 3,000 mg/L ($21,000 \mu\text{mol/L}$) [48], however, suggesting the possibility that multiple-dose activated charcoal in poisoned patients might provide some benefit in interrupting enterohepatic circulation. There are no published clinical prospective studies, from which to assess the efficacy of multiple-dose activated charcoal in patients with large acute ingestions or patients who have ingested an overdose of a delayed-release preparation. Life-threatening ingestions of VPA are many grams in amount such that VPA levels may rise despite attempts at giving MDAC. Therefore, The administration of activated charcoal may decrease gastrointestinal absorption if administered soon after ingestion. However, it is unknown if this affects either clinical course or outcome. Patients who ingest VPA may develop a decreased mental status while taking activated charcoal, and therefore it should be used cautiously, if at all, in nonintubated patients. Activated charcoal is unlikely to have an effect if given greater than 1 hour post ingestion.

Indications for ICU Admission in Valproic Acid Poisoning (Evidence Level III)

History of large-dose symptomatic acute ingestion

Rapidly decreasing level of consciousness
or presence of coma

Cerebral edema

Markedly abnormal liver function tests,
including elevated blood ammonia

Hypoglycemia

Metabolic acidosis

Cholestyramine does not decrease VPA gastrointestinal absorption clinically to a significant degree in humans [51].

Common Errors in the Treatment of Valproic Acid Poisoning

Omission of consideration of administration of L-carnitine

Omission of consideration of administration of N-acetylcysteine

Omission of consideration of use of high-flux hemodialysis

Monitoring for delayed absorption and toxicity

Hemodialysis

Despite the high percentage of VPA bound to plasma proteins at therapeutic concentrations, hemodialysis may have a role in VPA poisoning. High-flux hemodialysis alone without hemoperfusion was effective in one patient with coma, hypotension, lactic acidosis, and a serum VPA concentration of greater than 1,200 mg/L [52]. At high serum concentrations of VPA, its protein-binding fraction decreases owing to saturation of albumin binding sites. For example, 32% is bound at 1,400 mg/L (9,800 $\mu\text{mol/L}$) [53], resulting in the potential for greater effectiveness of hemodialysis than in patients with VPA

concentrations in the therapeutic range when it is 85–95% bound to plasma proteins. In one patient, high-flux hemodialysis of 6 h duration reduced serum VPA concentrations from 940 to 165 mg/L (6,580–1,155 $\mu\text{mol/L}$) [54]. Case reports of extracorporeal methods indicate that this approach rapidly decreases elevated VPA serum concentrations [55–58]. Peritoneal dialysis does not seem to be effective, however [59]. Although hemodialysis is effective in reducing plasma VPA concentrations, it may not affect outcome because most patients survive with supportive care, generally consisting of airway support and mechanical ventilation. In patients with extremely elevated VPA serum concentrations, hemodialysis perhaps may decrease the duration of coma and perhaps may reduce complications by enhancing drug clearance.

Naloxone

Anecdotal case report experience suggests that naloxone may provide some benefit in some, but not all, patients with VPA-induced coma and decreased ventilatory function (respiratory depression) [60]. Naloxone is relatively safe; its benefit-to-risk ratio is favorable for use in most patients with coma and ventilator depression. The fraction of patients with VPA poisoning who may respond at least to some extent to administration of naloxone is not reported.

L-Carnitine

VPA therapy and overdose both may result in decreased plasma carnitine concentrations, which decreases beta-oxidation [25, 61–65]. In patients with VPA-induced hepatotoxicity, L-carnitine treatment is reported to result in 48% survival in 42 patients compared with 10% survival in 50 patients treated with aggressive supportive care alone [66]. There was greater survival with intravenous L-carnitine compared with enteral L-carnitine, which is likely related to the 15%

enteral bioavailability of L-carnitine. The dose of L-carnitine recommended is 50–100 mg/kg/day typically for a few days until there is evidence of significant clinical improvement. The optimal dose has not been established. L-carnitine administration is reported to lower elevated blood ammonia concentrations toward the normal range in therapeutic dose VPA-treated children [67]. L-carnitine treatment, which is considered relatively safe, is recommended for patients with VPA hepatotoxicity (evidence level II-3). D-Carnitine is not active, and D, L-carnitine may be associated with a myasthenia-like syndrome.

L-carnitine administration may be considered for most patients with VPA poisoning because of the associated reduction in plasma concentrations of carnitine in these patients, which occurs even in some patients treated with therapeutic doses of VPA. Recommended oral doses of L-carnitine for carnitine deficiency are 50–100 mg/kg/day in children and 1–3 g/day in adults. L-Carnitine should be administered intravenously in VPA-poisoned patients. There are no published studies that establish optimal doses of intravenous L-carnitine to be administered to patients with VPA poisoning. More recent studies add further support for administration of L-carnitine to patients with VPA toxicity [68–70].

N-acetylcysteine

Because the liver toxic metabolite 4-en-VPA is produced by oxidant cytochrome P-450 mechanisms and 4-en-VPA seems to be metabolized further by a cytochrome P-450 (probably CYP2E1) to a reactive and perhaps toxic intermediate metabolite, use of N-acetylcysteine (NAC) has been recommended (evidence level III). There are no controlled published prospective randomized clinical studies outcome data that demonstrate NAC to be an efficacious treatment for VPA hepatotoxicity or VPA-induced cerebral edema [71]. NAC is a plausible therapy for VPA hepatotoxicity and for VPA-induced delayed cerebral edema because of cytochrome P-450

production of a toxic metabolite of VPA (i.e., further metabolism of 4-en-VPA) (see Fig. 2). NAC is reported to offer benefit for the treatment of liver failure from multiple causes [72, 73]. A dosing regimen for NAC similar to that for acetaminophen hepatotoxicity would seem to be a reasonable approach.

Criteria for ICU Discharge in Valproic Acid Poisoning

Patient is awake enough to protect their airway

Hemodynamic stability

Improving liver function

Children, pregnant women, and the elderly are treated similarly for VPA poisoning. There is some evidence that L-carnitine is transported across the human placenta (evidence level II-2) [74].

Key Points in Valproic Acid Poisoning (Evidence Level II-3)

1. Early recognition of hepatotoxicity in patients on long-term therapeutic dosing improves outcome.
2. Early use of L-carnitine improves survival in patients with VPA hepatotoxicity.
3. High-flux hemodialysis is efficacious in enhancing drug clearance. It is not known if it affects outcome.

Parkinson disease, named after James Parkinson who first described the disorder in 1817, is a chronic, progressive neurologic disorder clinically characterized by a combination of tremor, rigidity, and bradykinesia [1, 2]. Estimates of the incidence of Parkinson disease range from 5 to 20 new cases per 100,000 individuals per year, occurring with a slightly greater frequency in middle-aged and elderly men of European and North American descent [1, 3]. The cause of Parkinson disease is unknown, but it has been observed in humans and induced in primates by exposure to 1-methyl-4-phenylpyridine (MPP⁺), a metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which poisons complex I of the mitochondrial electron transport chain (Fig. 1) [4]. Other risk factors associated with the development of Parkinson disease include oxidant stress, reduced glutathione stores, tobacco smoking (linked inversely to the development of Parkinson disease), and caffeine consumption (correlated with reduced risk) [3, 4]. Current scientific evidence suggests that Parkinson disease does not have a substantial genetic component [3].

Pars compacta neurons located in the substantia nigra are responsible for dopaminergic input to the striatum, located within the basal ganglia (Figs. 2 and 3). Dopamine activates excitatory D₁ receptors in the striatum in a direct (monosynaptic) pathway and inhibits inhibitory striatal D₂ receptors in an indirect (polysynaptic) pathway (Table 1). With loss of dopaminergic nigral cells and subsequent striatal dopamine depletion, there is decreased activity of the direct pathway and increased activity of the indirect pathway. The net result of dopamine loss is reduced thalamic excitation of the motor cortex, resulting in the clinical manifestations of Parkinson disease [1, 5].

The hallmark clinical features of Parkinson disease are resting tremor, cogwheel rigidity, and bradykinesia. Patients with Parkinson disease may manifest other motor signs and symptoms, including masked facies and gait abnormalities. Nonmotor signs and symptoms such as sensory abnormalities, autonomic dysfunction, dementia, and depression are also characteristic [1].

Medical treatment of patients with Parkinson disease can be categorized as either symptomatic or preventive. Symptomatic therapy involves

Fig. 1 Mechanism of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced degeneration of nigrostriatal dopamine neurons. MPTP is converted by monoamine oxidase B (MAOB) within astrocytes or other nondopaminergic neurons to the reactive intermediate 1-methyl-4-phenylpyridine (MPP⁺). MPP⁺ is taken up into the dopaminergic neuron by the dopamine (DA) transporter. Within the dopaminergic neuron, MPP⁺ acts on

mitochondria to inhibit mitochondrial respiration, which results in cell death. ADP adenosine diphosphate, ATP adenosine triphosphate (From Gudelsky GA: Drugs for the treatment of Parkinson's disease. In Brody TM, Larner J, Minneman KP [eds]: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, p 386)

Fig. 2 Parkinson disease and the neural circuitry of the basal ganglia. (a) The striatum is the principal input structure of the basal ganglia. Striatal D₁-receptors mediate an excitation of a direct output pathway to the medial globus pallidus (MGP). Striatal D₂-receptors mediate an inhibition of an indirect output pathway projecting through the lateral globus pallidus (LGP) and subthalamic nucleus (STN) to the substantia nigra pars reticulata (SN_{pr}) and MGP. (b) Loss of dopaminergic input to the striatum resulting from degeneration of nigrostriatal dopamine neurons results in a decrease in the activity of the direct output

pathway and an increased activity of the indirect output pathway. The net effect is an increased inhibitory outflow from the SN_{pr} and MGP to the thalamus. This outflow ultimately results in reduced excitatory input to the cerebral cortex. *Thin lines* normal neuronal activity, *dashed lines* reduced activity, *thick lines* increased activity, SN_{pc} substantia nigra pars compacta (From Gudelsky GA: Drugs for the treatment of Parkinson's disease. In Brody TM, Lerner J, Minneman KP [eds]: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, p 390)

administration of medications, including levodopa/carbidopa, anticholinergics/antihistamines, amantadine, dopamine agonists (e.g., bromocriptine, rotigotine, pramipexole), monoamine oxidase (MAO) B inhibitors (e.g., selegiline, rasagiline mesylate), catechol-*O*-methyltransferase (COMT) inhibitors (e.g., entacapone), antidepressants, and atypical antipsychotics. Preventive treatment is targeted at slowing or halting the development and progression of the disease and includes medications such as MAO B inhibitors, dopamine agonists, antioxidants, anti-inflammatories, and antiapoptotic agents. Novel therapies currently under investigation include injection of pluripotent stem cells in an attempt to regenerate degenerative nigra cells, as well as targeted gene therapies [6–8]. This chapter provides an overview of the

various classes of medications commonly implemented to treat patients with Parkinson disease and the tools with which to evaluate and treat toxicities associated with these medications in the critical care setting. Because patients who experience the toxic effects of antiparkinson agents are typically elderly, the critical care provider is advised to also consider the toxicity risks associated with advanced age (see ► Chap. 8, “Geriatric Poisoning”).

Levodopa/Carbidopa

The amino acid levodopa (L-3,4-dihydroxyphenylalanine, Fig. 4) is the metabolic precursor of all catecholamines and normally is produced from

tyrosine by the action of tyrosine hydroxylase (Fig. 5). It is decarboxylated to dopamine by dopa decarboxylase [9]. It has been stated that, “Levodopa is the most reliable and effective symptomatic treatment for Parkinson disease. Almost all patients with true idiopathic Lewy body Parkinson disease respond to levodopa treatment. Indeed, failure to respond suggests an alternative diagnosis” [4]. Treatment of Parkinson disease patients with levodopa is associated with decreased morbidity and mortality compared with treatment in the “pre-levodopa era” [2].

Fig. 4 Chemical structure of levodopa

Pharmacokinetics

Levodopa is well absorbed from the gastrointestinal tract, but drug bioavailability may be limited by many factors. Coingestion of other relatively large amino acids hinders levodopa absorption via saturation of the amino acid transport system in the proximal small intestine. Additionally, gut wall decarboxylase metabolizes 50–75% of orally administered levodopa before it reaches the systemic circulation. Delayed gastric emptying, which may occur with consumption of large meals or concomitantly administered anticholinergic medications, delays drug delivery to the small intestine and retards the onset of peak plasma concentrations [9].

The volume of distribution of levodopa is approximately 0.9–1.6 L/kg, with an apparent half-life of 0.78–1.74 h. It is metabolized in the periphery by COMT to the inactive metabolite 3-*O*-methyldopa (3-OMD) and is excreted primarily in the urine as unchanged dopa and in the form of several metabolites, including homovanillic acid and dopamine [9].

Fig. 5 Sites of action of antiparkinsonian agents to facilitate dopaminergic function. Levodopa (L-dopa) enhances the synthesis and ultimately the release of dopamine (DA). Amantadine facilitates the release of dopamine. Dopamine agonists directly activate dopamine receptors (D₁ and D₂) on the postsynaptic cell. Selegiline inhibits the metabolism

of dopamine in nondopaminergic neurons or glia or both (From Gudelsky GA: *Drugs for the treatment of Parkinson's disease*. In Brody TM, Larner J, Minneman KP [eds]: *Human Pharmacology: Molecular to Clinical*, 3rd ed. St. Louis, Mosby, 1998, p 388)

Levodopa effectively penetrates the blood–brain barrier. When administered alone, however, levodopa is decarboxylated nearly completely in the peripheral circulation to dopamine, which does not penetrate the blood–brain barrier. In addition, common gastrointestinal side effects of levodopa (such as nausea and vomiting) occur secondary to the conversion of dopa to dopamine in the periphery and resultant dopamine-mediated stimulation of postrema areas not protected by the blood–brain barrier [2]. Coadministration of a dopa decarboxylase inhibitor, such as carbidopa or benserazide, minimizes peripheral conversion of levodopa to dopamine, promoting maximal exposure of the brain to the desired agent and minimizing untoward gastrointestinal effects [10]. Another benefit gained from dopa decarboxylase inhibitor administration is the 70–80% reduction in daily levodopa dose needed for clinical efficacy [9].

Pharmacokinetics of Levodopa (Dopar; Sinemet, in combination with carbidopa)

Volume of distribution: 0.9–1.6 L/kg

Protein binding: none

Metabolites: dopamine, homovanillic acid, dopa

Plasma elimination half-life: 0.78–1.74 h

Clinical Presentation

Adverse Effects

Patients receiving therapeutic doses of levodopa commonly experience anorexia, nausea, and vomiting thought to be mediated by dopaminergic stimulation of the medullary emetic center [11]. Because dopamine is an active catecholamine possessing α - and β -adrenergic agonist properties, administration of levodopa may cause tachycardia, cardiac dysrhythmias, hypertension, and, later, orthostatic hypotension [11]. Additionally, patients receiving levodopa may develop behavioral disturbances, including confusion, delirium, hallucinations, anxiety, and depression [11]. Long-standing use of levodopa may result in the development of dyskinesias such as chorea,

dystonia, and myoclonus. Levodopa-induced dyskinesia occurs in approximately 50–75% of Parkinson patients after 5–10 years of therapy [12]. The mechanism of the dyskinesia has been suggested to be related to pulsatile stimulation of striatal dopamine receptors, with a resulting “downflow supersensitivity” [13].

Levodopa is a phenylethylamine compound and is structurally related to other central nervous system (CNS) stimulants and sympathomimetic drugs (e.g., amphetamine). Similar to other drugs in this class, levodopa is subject to abuse, which is well-described in Parkinson patients who desire a particular psychological benefit from the medication [14]. Slow discontinuation and then reintroduction of levodopa to the desired clinical endpoint may prove successful in treating this problem.

Significant drug–drug interactions with levodopa are relatively uncommon; however, any substance or medication that alters gastric motility or emptying (e.g., presence of food, anticholinergic medications) may change levodopa absorption and plasma concentrations. Penicillamine increases plasma levodopa levels by greater than 50% by enhancing levodopa absorption [15]. Several other drugs have been shown to accentuate the clinical manifestations of Parkinson disease and may interfere with levodopa therapy. Reserpine and tetrabenazine can reduce dopaminergic function by depleting presynaptic dopamine stores and may compromise and interfere with levodopa’s efficacy. Methylodopa, after conversion to methyl dopamine by dopa decarboxylase in presynaptic dopaminergic nerve terminals, can serve as a partial dopamine agonist and can competitively interfere with levodopa at the D_2 dopamine receptor. Coadministration of dopamine antagonists, such as high-potency neuroleptics or metoclopramide, can offset levodopa efficacy and exacerbate manifestations of underlying Parkinson disease. Calcium channel-blocking agents (flunarizine, verapamil, diltiazem, amlodipine, manidipine) also may exacerbate parkinsonism due to interference with presynaptic striatal dopamine release [15]. Several other medications, including amiodarone, valproic acid, vigabatrin, cytosine, methotrexate, dacarbazine, cisapride, meperidine, isoniazid, and amoxapine, may cause or worsen parkinsonism [15].

There is a hypothetical concern regarding levodopa neurotoxicity after long-term administration resulting from the propensity of the drug, once metabolized, to form free radicals. This potentially toxic phenomenon has been shown *in vitro* but has not been substantiated clinically [2, 16].

Overdose and Toxicity

Although the adverse effects of levodopa therapy are well described, there is a relative paucity of literature describing acute levodopa overdose. Delmas et al. [17] described a case of a patient who ingested carbidopa; additionally, Hoehn and Rutledge [18] described a 61-year-old Parkinson disease patient who ingested approximately 100 g of levodopa and presented with marked confusion, agitation, “jerking movements,” restlessness, and initial hypertension followed by orthostatic hypotension. Both patients did well with supportive care. A case report of a woman with no previous history of Parkinson disease who ingested approximately 15–17 tablets of levodopa/carbidopa (Sinemet®), ibuprofen, carisoprodol, and hydrocodone/acetaminophen described her as lethargic with choreiform movements. These choreiform movements were unaffected by administration of morphine sulfate and diazepam; pancuronium was administered intermittently for almost 60 h until the patient’s dyskinesias resolved. She was treated supportively and recovered without apparent sequelae [11].

Additionally, Parkinson patients can present not only after levodopa overdose but also with other levodopa-induced problems. Dyskinesias and motor fluctuations are common late complications of Parkinson disease and may be related not only to progression of disease but also to fluctuations in serum levodopa concentrations [19]. Levodopa-induced dyskinesias may be ballistic, dystonic, myoclonic, or choreoathetotic and can affect any muscle group, including muscles involved with ventilatory function. Motor fluctuations range from “on” stable intervals, during which Parkinson symptoms are controlled, to “off” periods, when the patient may experience disabling immobility, tremor, or postural instability. In addition, during the “off” periods, nonmotor features such as autonomic instability,

confusion, anxiety, and (rarely) neuroleptic malignant syndrome from relative lack of central dopamine may be seen [19]. Several emergent complications may arise from these various disorders, including rhabdomyolysis and respiratory failure from aspiration or ineffective ventilation.

Acute dystonic reactions and neuroleptic malignant syndrome, thought to stem from D₂ receptor antagonism, can be seen in patients in whom levodopa is withdrawn abruptly [20, 21]. This syndrome generally responds to reinstitution of levodopa therapy [22]. Neuroleptic malignant syndrome is discussed in detail in the chapter by that name.

Diagnosis

The initial diagnostic approach to a poisoned patient relies heavily on the history and physical examination. For a patient who has overdosed, it is recommended that several initial laboratory studies be obtained, including serum electrolytes, serum acetaminophen and salicylate assays, and an electrocardiogram (ECG). Occasionally, a urine toxicological assay may be deemed necessary. The general diagnostic considerations in the evaluation of overdose patients are discussed in ► Chap. 2, “The Diagnostic Process in Medical Toxicology.” The toxicological differential diagnosis is broad and includes poisoning by sympathomimetic agents (e.g., amphetamines (see ► Chap. 72, “Amphetamines and Their Derivatives”), salicylates (see ► Chap. 63, “Salicylates”), or thyroid hormone.

In the case of acute ingestion of levodopa, the diagnosis is reached primarily by history and physical examination. Stuerenburg and Schoser [23] reported the value of measuring plasma concentrations of levodopa and 3-OMD (resulting from the ortho-methylation of levodopa) to the diagnosis and care of a patient who overdosed on levodopa/carbidopa. Hoehn and Rutledge [18] reported the utility of measuring levodopa metabolites, such as dopamine dihydroxyphenylacetic acid, homovanillic acid, and norepinephrine, in urine to confirm levodopa exposure and to follow the eventual clearance of levodopa as it parallels clinical improvement. The availability of these assays

in most clinical care settings is limited, however, and they are not essential to patient management, which is almost entirely supportive.

Parkinson disease patients presenting with possible levodopa-induced clinical findings should be evaluated for other nontoxicologic diagnoses such as sepsis. An infectious disorder, such as pneumonia or urinary tract infection, or another systemic disease process such as heart failure can alter the patient's sensitivity to levodopa, triggering fluctuation in motor function [19]. Appropriate diagnostic and laboratory tests should be tailored to the individual clinical presentation and may include a chest radiograph (also frequently needed for aspiration concerns), complete blood count, blood cultures, cardiac enzymes, and urinalysis, in addition to those studies previously mentioned. Additionally, severe dyskinesia and neuroleptic malignant syndrome may promote rhabdomyolysis and myoglobinuric renal injury; serum creatine phosphokinase, electrolytes, blood urea nitrogen, and creatinine concentrations should be considered among the laboratory values obtained. Given the increased risk for thromboembolic disease in those patients with chronically decreased mobility, noninvasive vascular studies, such as lower extremity Doppler ultrasound, may be indicated.

Treatment

Treatment of the acutely levodopa-poisoned patient is largely supportive. The experience with levodopa overdose is limited, and suggestions regarding management of toxicity are based mainly on theoretical concerns. In the few instances of levodopa overdose that are documented in the medical literature, patients did well with supportive care alone.

**Indications for ICU Admission
in Antiparkinsonian Drug Toxicity**
Levodopa/Carbidopa
Severe agitation
Autonomic instability
Altered level of consciousness
Uncontrollable severe movement disorder
Neuroleptic malignant syndrome

As in all poisonings, attention initially should be focused on the patient's airway and circulatory status. If agitation is severe and uncontrollable, the airway should be secured. A dose of oral activated charcoal may reduce further systemic drug absorption when administered within the first few hours of ingestion. It is unknown, however, whether the administration of activated charcoal alters the clinical course or outcome in these patients. There is no published evidence to support efficacy or clinical benefit of gastric lavage.

Hypertension has been described in the acute phase of levodopa overdose and generally has been transient [11, 18]. If hypertension is persistent and severe, however, intravenous short-acting direct vasodilators such as sodium nitroprusside may be preferred over β -blockers because of the theoretical concern for unopposed α -adrenergic effects of levodopa poisoning. Hypotension should be treated initially with intravenous crystalloid and then, if hypotension is persistent, with intravenous direct vasopressor (such as norepinephrine) infusion. Catecholamines with relative α -adrenergic potency generally are preferred because dopamine-induced, β -adrenergic-mediated vasodilation may occur in patients with hypotension refractory to volume resuscitation (Evidence Level III).

Agitation and dyskinesia may be managed initially with intravenous benzodiazepines, such as lorazepam or diazepam, titrated to mild sedation. If necessary, neuromuscular blockade may be implemented for control of extreme movement disorder or severe combativeness.

Treatment of other acute, subacute, or chronic manifestations of levodopa poisoning should be carried out on the basis of the specific presentation. Associated medical illness such as an infectious process must always be considered and treated expeditiously. Another essential facet of therapy is directed at modification of the patient's antiparkinsonian maintenance regimen, which may include discontinuation or reduction of levodopa dosage during periods of dyskinesia or increased levodopa administration during clinical "off" periods. Additionally, implementation of other antiparkinson drugs (see the remainder of this chapter), such as dopamine agonists or

COMT inhibitors, may be indicated, depending on the clinical situation. Benzodiazepines and atypical neuroleptics may be helpful in reducing the severity of dyskinesia. In the case of Parkinson disease patients with acute psychosis, all antiparkinsonian medications should be withheld, and benzodiazepines should be administered for agitation [19]. Standard neuroleptics probably should be avoided because of their potential proparkinsonian effects. Consultation with a neurologist is recommended when adjustments are being made to the patient's medications.

Key Points in the Evaluation and Treatment of Antiparkinsonian Drug Toxicity
Levodopa/Carbidopa

1. Clinical toxicity is similar to that of sympathomimetic drugs (see ► [Chap. 41, "Sympathomimetic Agents"](#)), including delirium, dyskinesia, tachycardia, and hypertension.
2. Abrupt withdrawal after long-term administration may result in acute extrapyramidal manifestations.
3. Treatment of acute toxicity is mainly supportive.

Anticholinergic Agents

Anticholinergic medications have been used in the treatment of Parkinson disease dating to the mid-nineteenth century and include trihexyphenidyl (Artane[®]), procyclidine (Kemadrin[®]), biperiden (Akineton[®]), orphenadrine (Disipal[®], Norflex[®]), and benztropine (Cogentin[®]). The use of anticholinergic drugs in Parkinson patients is directed at the imbalance between cholinergic and dopaminergic tone in their basal ganglia and is supported by their clinical efficacy. The anticholinergic agents employed are competitive antagonists at cholinergic muscarinic receptors throughout the body [24] and, in some cases, are inhibitors of dopamine reuptake, potentially exerting a dual action in restoring CNS neurotransmitter balance. The

actual mechanism of action of anticholinergic medications in Parkinson disease is uncertain, however [2].

Pharmacokinetics

In general, anticholinergic antiparkinsonian medications are well absorbed from the gastrointestinal tract, with peak plasma concentrations reached within 1–3 h [9]. A paucity of published data exists regarding the distribution and metabolism of these drugs. Trihexyphenidyl seems to follow a two-compartment model after ingestion with first-order terminal elimination kinetics [9]. Procyclidine may undergo "some first-pass metabolism, presumably in the liver, based on estimates of oral bioavailability." [9] Biperiden is eliminated via hepatic metabolism "with no unchanged drug being excreted in the urine" [9].

Some anticholinergic medications, such as benztropine and orphenadrine (Fig. 6), are structurally similar to the antihistamine diphenhydramine. Orphenadrine is the *O*-methyl analogue of diphenhydramine, allowing for prediction of additional toxicities (e.g., sodium channel blockade at high doses) based on shared structure–activity relationships [9].

Clinical Presentation

Adverse Effects

Adverse effects of anticholinergic medications are encountered commonly by patients and frequently limit their utility in clinical practice. This situation is particularly true in elderly patients, in whom side effects may be pronounced because of a myriad of concomitant physiologic perturbations (such as the presence of dementia or autonomic insufficiency) and other prescribed medications. Central anticholinergic effects include confusion, memory difficulty, sedation, and hallucinations. Peripheral effects secondary to muscarinic inhibition include dry mouth/mucous membranes, constipation, urinary retention, precipitation of glaucoma, blurry vision, anhidrosis, and tachycardia [2, 24].

Fig. 6 Chemical structures of procyclidine, biperiden, orphenadrine, and benztropine

With the exception of the potential effects of anticholinergic drug-induced gastrointestinal dysmotility on absorption of other drugs, pharmacokinetic drug–drug interactions generally are not clinically relevant to their use in Parkinson patients. There are innumerable prescription and over-the-counter medications, however, that possess anticholinergic properties, adding to the adverse pharmacodynamic effects of these agents.

Overdose and Toxicity

Intentional overdose and abuse of anticholinergic agents used to treat Parkinson disease commonly are described in the medical literature. Drugs such as benztropine and trihexyphenidyl are abused for their hallucinogenic and euphoric effects [25].

The clinical presentation of anticholinergic toxicity results from blockade of central and peripheral muscarinic cholinergic receptors [25, 26]. Confusion, hallucinations, incoherent speech, and agitation are hallmark central effects of anticholinergic drugs. The peripheral effects include hyperthermia, tachycardia, dry axillae, decreased bowel sounds,

and urinary retention [25, 27]. In addition, the antihistaminic properties of benztropine and orphenadrine may cause lethargy and sedation. Benztropine-induced dystonic and dyskinetic reactions, similar to those of antipsychotics, also have been reported [28]. The anticholinergic syndrome is described in detail in the chapter on that syndrome.

Special mention is warranted regarding orphenadrine poisoning. In addition to its antihistamine and anticholinergic properties, orphenadrine has relatively potent sodium channel-blocking effects on the cardiovascular system, with significant potential in overdose for producing cardiac conduction disturbances, depressed myocardial contractility, hypotension, and ventricular dysrhythmias [29, 30].

Diagnosis

The diagnosis of anticholinergic syndrome is based on a thorough history and careful physical examination, focusing on features that may

distinguish acute antimuscarinic effects from features reflecting the presence of other toxidromes, particularly hyperadrenergic states. In the case of acute overdose, measurement of serum electrolytes and acetaminophen/salicylate concentrations is generally considered appropriate. Under some circumstances, additional diagnostic tests aimed at searching for coingestants may be indicated (see ► [Chap. 2, “The Diagnostic Process in Medical Toxicology”](#)). An ECG should be performed to assess cardiac rhythm and the presence of significant interval (e.g., QRS or QTc) prolongation, especially when dealing with orphenadrine poisoning.

Serum benztropine concentrations, although not readily obtainable in most clinical care settings, may be helpful in patients poisoned with this medication. Fahy and colleagues [27] reported following serial benztropine concentrations in a 38-year-old man who ingested a vial of 1-mg benztropine tablets; levels peaked at 100 µg/L (325 µmol/mL), and anticholinergic symptoms persisted until the serum concentration reached 9 µg/L (29 µmol/mL). A specific laboratory approach to anticholinergic poisoning may not only aid in the diagnosis of uncertain clinical presentations but also provide prognostic value.

Treatment

The chapter on the anticholinergic syndrome discusses the treatment of that syndrome in detail. In general, meticulous supportive care, including maintenance of an airway, supplemental oxygen, intravenous fluids to correct intravascular volume deficits, cardiac monitoring, and bladder catheterization, is indicated in most patients with anticholinergic syndrome [24, 31]. Particular attention should be focused on the detection of rhabdomyolysis secondary to agitation and impaired thermoregulation [27].

Decontamination with activated charcoal historically has been considered helpful because some anticholinergic medications, such as benztropine, undergo enterohepatic metabolism

and recirculation [24]. It is unknown, however, whether activated charcoal effectively absorbs benztropine [27]. Furthermore, activated charcoal has not been demonstrated to alter the clinical course or outcome of poisoned patients.

Physostigmine, a reversible inhibitor of central and peripheral cholinesterase activity, increases acetylcholine concentrations at nicotinic and muscarinic synapses [31, 33]. This drug has been used not only as an aid in the diagnosis of anticholinergic syndrome but also in the control of its severe neuropsychiatric manifestations. Although most cases of anticholinergic syndrome can be treated successfully with supportive care alone, closely monitored, conservative administration of physostigmine may be beneficial in controlling severe anticholinergic agitation or convulsions or both [34]. Adverse effects of physostigmine include bronchospasm, seizures, and severe cardiac conduction abnormalities. The clinical pharmacology of physostigmine is discussed in the chapter in the Antidote section devoted to this agent.

Amantadine

Amantadine (Fig. 7) is an antiviral drug that, by fortuitous discovery, was found to possess antiparkinsonian efficacy. The mechanism of action of amantadine is unclear, but many actions have been suggested, including stimulation of catecholamine release, dopamine reuptake blockade, dopamine receptor stimulation, muscarinic antagonism, and *N*-methyl-D-aspartate (NMDA) receptor antagonism [11]. In clinical studies, amantadine administration has been found to alleviate bradykinesia, rigidity, and tremor in Parkinson patients [2].

Fig. 7 Chemical structure of amantadine

Pharmacokinetics

Amantadine is well absorbed after oral administration [32]. The volume of distribution of amantadine is large, with estimates ranging from 6 to 10 L/kg, and it is believed to be highly protein-bound [9]. It is not significantly metabolized and is excreted unchanged in the urine through glomerular filtration and tubular secretion [9]. The plasma elimination half-life is approximately 12–18 h in healthy adults. The half-life can increase twofold, however, in the elderly or in patients with renal insufficiency [9, 32].

Pharmacokinetics of Amantadine (Symmetrel)

Volume of distribution: 6–10 L/kg

Protein binding: 0.67%

Metabolites: unchanged

Plasma elimination half-life: 12–18 h

Clinical Presentation

Adverse Effects

The most common adverse effects experienced in patients taking amantadine are confusion, insomnia, hallucinations, and nightmares. Less-troublesome side effects include ankle edema and livedo reticularis, which generally are well tolerated and do not limit treatment. Additionally and importantly, there may be acute worsening of Parkinson disease when amantadine is withdrawn abruptly [2]. The adverse effects of long-term amantadine therapy may be exacerbated by coadministration of anticholinergics or drugs that reduce its renal clearance, such as hydrochlorothiazide/triamterene [32].

Overdose and Toxicity

The toxic effects of amantadine overdose principally involve the CNS and cardiovascular system. Patients typically present with agitation, psychosis, and restlessness, in addition to the other central and peripheral signs of anticholinergic poisoning (see ► Chap. 23, “Anticholinergic

Syndrome”) [33]. Amantadine-induced coma has been reported [34]. Claudet et al. [35] also reported a case of status epilepticus associated with overdose of this agent.

Cardiovascular effects of amantadine toxicity include hypotension, bradycardia, cardiac conduction defects, QTc prolongation, and malignant ventricular dysrhythmias including torsades de pointes [36]. These findings may be explained by amantadine’s tricyclic amine structure and similarity to cardiotoxic cyclic antidepressants [37, 38].

Diagnosis

Patients presenting with amantadine poisoning should be evaluated with routine laboratory tests and diagnostic studies previously mentioned for other antiparkinson medications. Patients should be placed on a cardiac monitor and an ECG obtained to detect the initial presence or later development of significant QRS widening, QTc prolongation, or dysrhythmia.

Serum amantadine concentrations have a confirmatory role in establishing the diagnosis of amantadine poisoning. Plasma concentrations greater than 1000 ng/mL (>6.6 nmol/mL) have been associated with CNS toxicity. The generally accepted therapeutic upper limit for this value is 300 ng/mL (2.0 nmol/mL) [32, 39].

Treatment

Treatment of amantadine poisoning consists mainly of supportive care. Intravascular volume replacement should be initiated and maintained at a rate that supports adequate urine output. Amantadine-induced ventricular dysrhythmias should be managed pharmacologically, first with lidocaine in standard treatment doses; class IA antidysrhythmics should be avoided because of their potential for exacerbation of cardiac conduction and repolarization abnormalities [37]. The management of torsades de pointes, discussed in ► Chap. 22, “Toxicant-Induced Torsade de Pointes,” is managed best with

defibrillation and subsequent parenteral magnesium sulfate or overdrive pacing. The onset of amantadine-induced cardiotoxicity may be delayed for 48 h after ingestion; it is recommended that symptomatic patients undergo extended cardiac monitoring [37].

Indications for ICU Admission in Antiparkinsonian Drug Toxicity

Amantadine

*Same as anticholinergic agents (see ► Chap. 23, “Anticholinergic Syndrome”)
Cardiac dysrhythmia (especially QTc prolongation, torsades de pointes)*

Administration of oral activated charcoal may reduce systemic absorption of amantadine if given within the first few hours after ingestion. Multiple-dose activated charcoal treatment has been described anecdotally for amantadine toxicity 24 h after ingestion [40]; however, it has not been subjected to further study in this setting and carries the risks associated with its use in anticholinergic poisoning (see ► Chaps. 3, “Therapeutic Approach to the Critically Poisoned Patient” and “► 23, Anticholinergic Syndrome”). Routine use of oral activated charcoal is not recommended.

Physostigmine has been used successfully for control of severe amantadine-induced agitation [41]. The use of physostigmine may lead to cholinergic crisis, however. Because physostigmine has been associated with asystolic arrest in cyclic antidepressant overdose, it should be avoided when significant cardiac conduction disturbance is evident [40]. A benzodiazepine, such as diazepam or lorazepam, would be the initial anticonvulsant of choice for amantadine-induced seizures.

Key Points in the Evaluation and Treatment of Antiparkinsonian Drug Toxicity

Amantadine

1. Major clinical manifestations of toxicity are anticholinergic syndrome, cardiac conduction disorder (e.g., QTc

prolongation), and ventricular dysrhythmia (e.g., torsades de pointes).

2. Administration of classes IA, IC, and III antidysrhythmic drugs should be avoided.

Selegiline

Monoamine oxidase is responsible for the central (intraneuronal) and peripheral (intestinal and hepatic) degradation of dopamine (Fig. 8). The enzyme exists in two forms, A and B, and is found in the CNS and in peripheral tissue [42]. MAO A activity is found predominantly in the liver and intestine, and MAO B activity is found mainly in the brain, liver, and platelets [43]. Irreversible and selective inhibition of MAO B by selegiline (Fig. 9) increases the duration of action of levodopa in Parkinson patients and may increase the “on” time in advanced cases [2]. This action also may reduce levodopa dosing requirements [2]. Selective MAO B inhibition occurs at therapeutic doses (10 mg/day), but selectivity may be lost at higher doses [15]. Selegiline also is used as a potentially neuroprotective agent in Parkinson patients based on its ability to block the MAO B-mediated oxidation of certain substrates (e.g., MPTP) to neurotoxic free radical species (e.g., MPP⁺) (Fig. 10; see Fig. 1) [2]. It has been speculated that administration of selegiline may retard striatal degeneration in Parkinson disease by inhibiting the formation of oxygen free radicals during CNS dopamine metabolism [2].

Pharmacokinetics

Selegiline is absorbed rapidly after oral administration and attains peak serum concentration within 0.5–2 h [42]. Selegiline has a volume of distribution of approximately 1.9 L/kg and exhibits an elimination half-life of approximately 2 h [44]. The drug’s major metabolites, L-methamphetamine and L-amphetamine, have longer half-lives of 29.5 and 17.7 h, respectively [45].

Fig. 8 The main pathways for dopamine metabolism in the brain. *COMT* catechol-*O*-methyltransferase, *MAO* monoamine oxidase

Fig. 9 Chemical structure of selegiline

Pharmacokinetics of Selegiline (Eldepryl)

Volume of distribution: 1.9 L/kg

Protein binding: 94%

Metabolites: L-amphetamine, L-methamphetamine

Plasma elimination half-life: 2 h

Clinical Presentation

Adverse Effects

Adverse effects of selegiline include CNS stimulation, insomnia, hallucinations, nausea, and vomiting. In addition, by inhibiting levodopa breakdown, selegiline may worsen levodopa-induced dyskinesia [45]. Orthostatic hypotension also has been reported with coadministration of selegiline and levodopa in Parkinson patients [46]. Additionally, if taken at higher daily dosages, selegiline may inhibit MAO A and exhibit toxicities similar to those of the less-selective antidepressant MAO inhibitors (see ► Chap. 50, “Monoamine Oxidase Inhibitors”).

Case reports have described significant drug–drug interactions of selective serotonin reuptake inhibitors, tricyclic antidepressants, and

Fig. 10 Mechanism of the potential neuroprotective effect of selegiline on the progressive neurodegeneration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced toxicity and Parkinson disease. Selegiline, an

inhibitor of monoamine oxidase B (MAOB), blocks the formation of the reactive intermediate 1-methyl-4-phenylpyridine (MPP⁺) from MPTP and the formation of hydroxyl free radicals from the oxidation of dopamine

selegiline, causing signs and symptoms resembling serotonin syndrome, which is discussed in more detail in the chapter on that topic. This syndrome results from blockade of serotonin metabolism by MAO and excessive stimulation of brain stem and spinal cord 5-hydroxytryptamine (5-HT_{1A} and 5-HT₂) receptors [47, 48]. This type of clinical presentation has been described with concomitant use of selegiline and meperidine, causing restlessness, agitation, delirium, and hyperthermia [15].

Overdose and Toxicity

An extensive literature review, including multiple case series of MAO inhibitor overdoses, identified one published case of selegiline overdose. It is largely presumed and not supported by published clinical experience that selegiline overdose would

inhibit MAO A and MAO B and produce a syndrome clinically similar to that of an antidepressant MAO inhibitor overdose. Toxicity from MAO inhibitors is discussed in more detail in ► [Chap. 50, "Monoamine Oxidase Inhibitors"](#). Fujita et al. [49] described a case of a patient with reported selegiline overdose who developed hyperthermia and recovered with supportive care alone. Extensive quantitative analyses of L-amphetamine metabolites were performed; however, selegiline concentrations were not specifically measured.

Diagnosis and Treatment

Analysis of urine should detect the presence of methamphetamine and amphetamine after selegiline ingestion. So-called chiral assays that

can distinguish the illicit D- from the L-isomeric form associated with selegiline use are commercially available. Appropriate therapeutic interventions for acute MAO inhibitor poisoning and serotonin syndrome are outlined in the chapters dealing with those topics.

Indications for ICU Admission in Antiparkinsonian Drug Toxicity

Selegiline

Hyperthermia
Autonomic instability
Serotonin syndrome
Severe agitation
Delirium
Rhabdomyolysis

Key Points in the Evaluation and Treatment of Antiparkinsonian Drug Toxicity

Selegiline

1. Interactions with other agents (e.g., sympathomimetic compounds, selective serotonin reuptake inhibitors) may result in excess adrenergic or serotonergic tone, clinically manifested as a sympathomimetic toxidrome or serotonin syndrome.
2. Overdose is characterized by toxicity similar to that of other MAO inhibitors (see ► Chap. 50, “Monoamine Oxidase Inhibitors”).
3. Selegiline’s major metabolites, L-methamphetamine and L-amphetamine, can be distinguished readily from the frequently illicit dextrorotatory forms of the same compounds by isomeric (chiral) determination.

Dopamine Agonists

Dopamine receptor agonists used in the treatment of parkinsonism are medications that, because of their dopamine-like molecular structure, directly

stimulate striatal postsynaptic D₂ receptors. They are regarded as some of the most effective drugs to treat Parkinson disease, second only to levodopa [45]. Traditionally, dopamine agonists have been used as adjuncts to levodopa in patients with Parkinson disease. Initiation of dopamine agonists as first-line therapy may postpone the need for levodopa therapy, however, providing overall reduction of the risks of levodopa-induced dyskinesia [2].

There are several advantages of dopamine agonists over levodopa: (1) they do not require conversion to an active metabolite to exert their pharmacologic effect, (2) circulating amino acids do not compete for their absorption and transport to the brain, (3) they have longer half-lives, (4) they do not undergo oxidative metabolism and do not produce potentially damaging oxygen free radicals, (5) they can target specific dopamine receptor subtypes, and (6) they offer a larger therapeutic window with decreased risk of dyskinesia [2]. Several dopamine agonists are currently available, including bromocriptine (Parlodel), pergolide (Permax), pramipexole (Mirapex), ropinirole (Requip), cabergoline (Cabaser, Dostinex), and lisuride (Dopergin) [50].

Pharmacokinetics

Bromocriptine (Fig. 11) is a potent D₂ receptor agonist, but it also possesses D₁ and 5-HT₂ agonist properties. It is absorbed rapidly after ingestion, is 90% metabolized by first-pass metabolism, and has a half-life of 3–8 h [50]. Bromocriptine is largely protein-bound and is excreted predominantly in the bile and feces [9].

Pergolide is almost ten times more potent than bromocriptine. It has a high affinity for D₂ receptors but also is a D₁, D₃, and α_2 receptor agonist [50]. Pergolide is well absorbed orally and has a half-life of approximately 3–7 h [10]. It is also 90% protein-bound [50].

Pramipexole binds to D₂ receptors primarily but also possesses affinity for a myriad of other receptors, including D₁, D₃, D₄, α_2 , acetylcholine, and serotonin receptors. Pramipexole has a half-life of

Fig. 11 Chemical structure of bromocriptine

about 8–12 h and is 15% protein-bound. Approximately 10% is metabolized, and the remainder is excreted unchanged in the urine [50].

Ropinirole binds to the D_2 receptor and has relatively insignificant agonist activity on other brain receptors. It is absorbed quickly and completely from the stomach and has an elimination half-life of approximately 6 h. Ropinirole is 40% protein-bound, metabolized by cytochrome P450 1A2 to inactive metabolites, and excreted in the urine [50].

Cabergoline is a D_2 agonist without effect on D_1 receptors. It has an elimination half-life of about 65 h [50].

Lisuride is a D_2 and 5-HT₂ agonist that has no D_1 activity. The onset of action is within 1 h after intravenous or subcutaneous administration. Lisuride exhibits an elimination half-life of approximately 1–7 h. There is no oral form because of minimal gastrointestinal absorption. Lisuride has effects comparable to those of dopa in treating Parkinson disease patients. This drug is available in Europe but not in the United States [50].

Significant drug–drug interactions may occur with the highly protein-bound dopamine agonists bromocriptine and pergolide. Coadministration of other highly protein-bound medications, such as warfarin or erythromycin, may result in elevation of dopamine agonist levels [15].

Pharmacokinetics of Dopamine Agonists

Bromocriptine (Parlodel)

Volume of distribution: 2 L/kg

Protein binding: 93%

Metabolites: –

Plasma elimination half-life: 3–8 h

Pergolide (Permax)

Volume of distribution: not available

Protein binding: >90%

Metabolites: extensive

Plasma elimination half-life: 27 h

Pramipexole (Mirapex)

Volume of distribution: 5.6–9 L/kg

Protein binding: 15%

Metabolites: 10

Plasma elimination half-life: 8–12 h

Ropinirole (Requip)

Volume of distribution: 7.5 L/kg

Protein binding: 40%

Metabolites: extensive

Plasma elimination half-life: 6 h

Cabergoline (Dostinex)

Volume of distribution: not available

Protein binding: 40–42%

Metabolites: extensive

Plasma elimination half-life: 65 h

Clinical Presentation

Adverse Effects and Chronic Toxicity

The side effects from dopamine agonists are similar to those of levodopa, including nausea, vomiting, orthostatic hypotension, hallucinations, psychosis, episodic somnolence (“sleep attacks”), and choreiform dyskinesias [2]. In addition, acute vasospastic crises (e.g., resulting in cerebral, coronary, or mesenteric ischemia), erythromelalgia, Raynaud’s phenomenon, and retroperitoneal and pulmonary fibrosis have been reported with the ergot dopamine agonists (e.g., bromocriptine) but are uncommon with the newer nonergot medications [2]. Serotonin syndrome theoretically may occur as a result of dopaminergic-mediated increase in serotonin release.

Overdose and Acute Toxicity

Most reported cases of dopamine agonist overdose involve bromocriptine. Taken in overdose, bromocriptine typically produces nausea, vomiting, hypotension, lethargy, paranoia, aggressive behavior, and hallucinations. The neuropsychiatric manifestations most likely can be explained by the fact that bromocriptine is a lysergic acid derivative, similar to LSD [51–53].

In a case report, a 17-month-old toddler who ingested her grandfather’s pramipexole exhibited lethargy, which resolved within 24 h [54]. Case reports of adult overdose printed in the manufacturer’s package insert describe ataxia, drowsiness, tachycardia, and vomiting, which all spontaneously resolved [54].

Diagnosis and Treatment

Indications for ICU Admission in Antiparkinsonian Drug Toxicity Dopamine Agonists

Uncontrolled agitation and delirium
Hypotension

Plasma bromocriptine concentrations vary widely among individuals on the same dose and do

not seem to correlate with clinical response or toxicity. Treatment of acute dopamine agonist overdose is largely supportive.

Key Points in the Evaluation and Treatment of Antiparkinsonian Drug Toxicity Dopamine Agonists
